The choice of detector depends on what information is required. If SEC is performed as routine evaluation of samples, requiring an approximately correct and repeatable result, then a modern differential refractometer calibrated with commercially available carbohydrate standards will suffice. When more detailed analysis is required, with higher accuracy, no calibration, and information such as degree of branching and radius of gyration, then a light-scattering detector should be used. Instruments are available based on either low-angle laser light scattering (LALLS) or multiple-angle laser light scattering (MALLS). LALLS eliminates the need for complicated mathematics required for higher angles, but is least suited for water-soluble materials. The reverse situation holds for MALLS. With both detectors the amount of attention required will be much greater than with a refractometer. However, further advances are anticipated, and such detectors may become as easy to handle as refractometers. Typical SEC profiles for a corn starch and an acid-thinned corn starch are given in Figure 3.

## Amylose/Amylopectin Content

The adsorption of iodine by amylose chains to give a deep blue complex is universally used to qualify starch, and to quantify amylose. For some industrial uses, it is imperative that starch hydrolysates contain no starch, and this can be confirmed by cooling the matrix to 5–10°C, adding 0.02 mol l<sup>-1</sup> iodine dropwise, and observing whether a blue color appears; the detection limit is 50 mg per kg.

Much has been published on ways of measuring iodine affinity, and care must be taken in applying the methodology. The simplest test is measurement of the 'blue value'. This entails dissolving 100 mg of starch in 10 ml of 1 mol l<sup>-1</sup> sodium hydroxide, making up to 100 ml, taking an aliquot, neutralizing, and developing the complex with iodine. Calibration is effected with amylose, and the intensity of the blue complex is measured at 620 nm. In all methods where calibration is effected with an amylose fraction, it should be representative of the amylose being analyzed. Iodine affinity is affected by chain length, degree of branching, and the nature of the amylopectin present. Fat also interferes, and the sample should preferably be defatted by refluxing for 24 h with 85% methanol solution. A more precise method is to measure the iodine affinity by potentiometric titration, using an amylose fraction separated from the native starch as calibrant.

Amylose/amylopectin ratio can be determined by measuring, respectively, the responses of the iodine

**Figure 3** Relative molecular mass distribution of corn starch, and an acid degraded corn starch. Samples dissolved in 90/10 dimethyl sulfoxide–water. Columns, Shodex S805/S804. Eluent,  $0.05 \text{ mol l}^{-1}$  NaOH. Detection, refractometer. Calibration, Shodex Pullulan kit P802.

complex at 620 and 550 nm. Another possibility is applying SEC analysis to a solution of the starch in dimethyl sulfoxide, adding iodine solution postcolumn, and measuring the absorption at the critical wavelengths. Either of these methods will require knowledge of the specific absorption of each fraction to realize quantification. An alternative is to debranch the amylopectin with isoamylase, subject the hydrolysate to SEC analysis, and calculate the carbohydrate profiles from the peak areas of the linear residues.

## Rheology

Probably the most important single physical property for application purposes is the viscosity profile of starch during its paste preparation. There are various types of viscometer available for evaluating its behavior but, whatever instrument is used, the conditions of paste preparation must be standardized and adhered to strictly, to obtain repeatability. When a dispersion of starch is heated, the granules absorb water and swell to many times their original volume before bursting. The peak viscosity during cooking is encountered at the maximum swollen state of the hydrated granules. At any moment during stirring and heating, there will be dissolved starch present that has leached out from broken granules. When all the swollen granules have burst, and the starch is dispersed, viscosity decreases as the temperature is raised.

Several types of viscometer are available that follow viscosity during paste preparation. Industry has widely adopted the Brabender viscometer. This has a rotational bowl and the sample exerts a force on fixed sensing elements that are dynamically balanced by a calibrated torsion spring, this causes an angular deflection of the sensing element shaft, which is continuously recorded. After the cooking, the temperature can be held at  $95^{\circ}\text{C}$ , cooled at a predetermined rate, then held at, say,  $50^{\circ}\text{C}$  to evaluate stability of the paste. The instrument is calibrated in arbitrary Brabender Units of viscosity. Typical viscosity curves of some native starches are shown in **Figure 4**.

As a relatively fast product quality and process control, the Scott Cup viscometer is often used. The starch paste is prepared according to a defined protocol and maintained at  $100^{\circ}\text{C}$ , then a fixed volume is timed as it passes through an orifice of defined dimensions. Sample weight is adjusted so that a constant flow time is obtained. Viscosity is then defined as weight Scott in grams. Of the universally used instruments, the Brookfield viscometer is extensively employed. Again, this technique is only of value if sample preparation is standardized.

## Modified Starches

Starch is modified to enhance its properties so as to extend application possibilities. The usual modification is to change the viscosity profile, although an ionic charge can be introduced, or emulsifying

**Figure 4** Brabender viscosity profiles of native starches (8%, w/v, dispersions): 1, potato; 2, waxy maize; 3, regular maize.

properties improved. There are strict regulations on the type that may be used in food, and it is imperative to have reliable methodology to determine type and degree of chemical substitution. The simplest modification is hydrolytic degradation with acid, which decreases the peak viscosity but increases the paste viscosity on storage. For such a product a viscosity profile is the important evaluation. Starch treated with hypochlorite under alkaline conditions exhibits a lower peak viscosity and has a clear, stable, low-viscosity paste. Carboxyl groups are introduced, and these can be quantified by titration with alkali, after conversion into the hydrogen form. Its anionic nature can be confirmed by staining the starch granules with methylene blue.

Of the esters, starch phosphate is produced by reaction with phosphorus oxychloride, polyphosphates, or metaphosphates; a cross-bonded product results. Total degree of substitution is determined by measuring the phosphorus content, and the mono- to disubstitution ratio can be calculated by potentiometric titration. Allowance is made for the natural phosphorus content of the starch. Treatment of starch with acetic anhydride produces starch acetate, which has improved paste stability over native starch. The acetyl group is very labile, and hydrolyses readily under mild alkaline conditions. When a known amount of alkali is used, the excess can be titrated and the ester function measured. This is not specific, however, and a method based on an enzymatic measurement of the acetate has been developed in an ISO work group. The modified starch is hydrolyzed under acidic conditions, which releases acetic acid and permits filtration of the resulting solution. Acetic acid is then measured by a commercially available enzyme test kit. Both bound and free acetyl groups can be measured, and the method is applicable

to granular and pregelatinized starches. The ISO collaborative exercise gave a reproducibility of 8% on 2% acetyl content.

Starch adipate, a cross-bonded starch for food use, is made by reaction with adipic anhydride, which is formed from adipic acid in the presence of excess acetic anhydride. It is also a labile ester, and after hydrolysis with alkali, followed by acidification, is extracted with ethyl acetate and silylated. Gas chromatographic analysis is performed on a capillary column of fused silica coated with dimethyl siloxane, film thickness 5  $\mu\text{m}$ . Pimelic acid is the internal standard. The method cannot differentiate between mono- and disubstitution. Alkyl succinate substitution can be determined using the same procedure as for adipate.

Starch ethers present a more difficult analytical problem because the bond is very resistant to attack. Carboxy-methyl starch substitution is determined by the titration method as used for carboxyl function. However, many of the commercial products are water soluble, and must first be precipitated with ethyl alcohol prior to analysis. Hydroxyalkyl starches can be analyzed using the Zeisel procedure based on decomposition with boiling hydroiodic acid. The alkyl iodide and corresponding olefin are formed, which can be measured by trapping in silver nitrate and bromine water, respectively. An alternative approach is to use proton nuclear magnetic resonance (NMR) spectroscopy, as the spectra from the methyl protons of the alkyl substitution permits quantification of the alkyl moiety. Cationic starches are commonly made from reaction with glycidyltrimethylammonium chloride, and substitution is usually determined from the nitrogen content; cationic nature is confirmed by staining with yellow-green SF dye. Proton NMR can also be used for this substituent.

## Dietary Fiber Measured as Nonstarch Polysaccharides in Plant Foods

**H N Englyst, G J Hudson, and M E Quigley**, Englyst Carbohydrates Research and Services Ltd., Southampton, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The original hypothesis on 'dietary fiber' was that a diet rich in unrefined plant foods was linked to a low incidence of 'Western diseases' (including diabetes). The hypothesis has been largely confirmed, and this is the background for the recommendations in national dietary guidelines for the consumption of a diet rich in fruit, vegetables, and whole-grain cereals. Unrefined plant foods are naturally rich in plant cell-wall material; the major constituents (~90%) of this material are non-starch polysaccharides (NSP). The naturally occurring plant cell-wall NSP content of foods is therefore a good marker for the unrefined plant foods embodied in the dietary fiber hypothesis and recommended in current dietary guidelines. In line with this, the Joint WHO/FAO Expert Consultation on Diet, Nutrition and the Prevention of Chronic Diseases (2000) specifies the recommended increased intake of fiber in the prevention of obesity, diabetes, and coronary heart diseases in terms of NSP.

The encapsulation of starch and sugars within the walls of the intact plant cell restricts the rate at which they are digested and absorbed in the small intestine, resulting in low glycemic index (GI) values and low rapidly available glucose (RAG) values (see Table 1). This ability to influence the rate and extent of digestion and absorption, and thus the physiological effects of other nutrients, is an important property of the cell wall in unrefined plant foods. This encapsulation effect is largely destroyed by excessive food processing, and cannot be reintroduced by the addition of 'fiber supplements'. It should be noted that some fiber supplements, when taken in large amounts, do lower the glycemic response via their effect on gastrointestinal function. This is especially true for the soluble materials, such as gums, which, due to their high viscosity, slow gastric emptying and restrict access of digestive enzymes to the food bolus. However, their effect is not related to their origin as plant material or even to their chemical identity (i.e., NSP); it is due solely to their physical properties (solubility and viscosity). Accordingly, the use of fiber supplements to augment the fiber-poor diets

typical of modern Western societies is not promoted by dietary recommendations, as these supplements are not part of the original hypothesis and do not impart the same overall beneficial properties as a diet rich in naturally occurring plant cell-wall material.

NSP, by definition, includes all the plant polysaccharides other than starch. For the reasons given above, NSP are divided into two broad classes in the classification and measurement scheme described here (Table 1): (1) the cell-wall NSP, which impart rigidity, and encapsulate and control the release of other nutrients, and (2) other NSP, including gums and refined preparations of cell-wall material, which occur in foods mainly as additives. There is no endogenous human enzyme for the hydrolysis of NSP, which are therefore nonglycemic, and all become available for fermentation in the large intestine.

The Englyst procedure for the measurement of NSP as a marker for 'dietary fiber' has evolved from the principles laid down by McCance and Widdowson, and later by Southgate. The procedure involves: (1) removal of starch by enzymatic hydrolysis, (2) collection of NSP by precipitation in ethanol, (3) release of the constituent sugars of NSP by acid hydrolysis, and (4) quantification of the NSP by measurement of the constituent sugars by gas chromatography (GC), high-performance liquid chromatography (HPLC), or colorimetry. Values for total, soluble, and insoluble NSP may be obtained.

### Applications of the Analytical Values

The detailed information obtained from the chromatographic methods, which identify and measure the individual constituent sugars, is particularly useful in studies of the relation between intakes of NSP and health. The results of NSP analysis, with values for the individual constituent sugars, are shown in Table 2 for a range of plant foods.

The spectrum of the constituent sugars is characteristic for various types of plant NSP and may indicate the origin of the NSP measured. The values for wholemeal wheat products are characterized by high levels of insoluble NSP in the form of cellulose (measured as insoluble NSP glucose) and arabinoxylans. Wholemeal wheat NSP are fermented slowly and incompletely, and exert a considerable effect on fecal bulk. White bread contains only 30% as much NSP as wholemeal bread, and this NSP is

**Table 1** Classification of dietary carbohydrates

	Main components	Comments
<i>Free sugars</i>		(Soluble in 80% ethanol; $\leq 2$ sugar units)
Mono- and disaccharides	Glucose, fructose, sucrose maltose, lactose	Glucose, maltose, and sucrose digested rapidly Fructose and lactose may, in part, escape digestion and absorption in the small intestine Physiological response depends on identity Free glucose + glucose from sucrose = free sugar glucose (FSG)
<i>Sugar alcohols</i>		(Soluble in 80% ethanol; $\leq 2$ sugar units)
Mono- and disaccharides	Sorbitol, inositol, mannitol galactitol, maltitol	Poorly absorbed in the small intestine. May reach the large intestine
<i>Short-chain carbohydrates</i>		(Soluble in 80% ethanol; $> 2$ sugar units)
Maltodextrins	$\alpha$ -Glucans	Partly hydrolyzed starch. Normally included in the measurement of starch
Resistant short-chain carbohydrates (nondigestible oligosaccharides)	Fructo-oligosaccharides, galacto-oligosaccharides, pyrodextrins, polydextrose	Escape digestion in the small intestine and are fermented to different extents. Some may stimulate growth of bifidobacteria. Physiological effect largely unknown
<i>Polysaccharides</i>		(Insoluble in 80% ethanol)
Starch	$\alpha$ -Glucans	The most abundant dietary carbohydrates
Rapidly digestible starch (RDS)	Rapidly released glucose	Rapidly digested in the small intestine RDS + rapidly released FSG = RAG
Slowly digestible starch (SDS)	Slowly released glucose	Slowly digested in the small intestine SDS + slowly released FSG = SAG
Resistant starch (RS)	RS <sub>1</sub> (physically inaccessible); RS <sub>2</sub> (resistant granules); RS <sub>3</sub> (retrograded starch)	The three types of RS escape digestion in the small intestine and are fermented to different extents. Physiological effect largely unknown
Non-starch polysaccharides (NSP)	Many different types of polysaccharides	Escape digestion in the small intestine and are fermented to different extents
Plant cell-wall NSP	Main constituents: arabinose, xylose, mannose, galactose, glucose, uronic acids	Encapsulate and slow absorption of nutrients. Good marker for naturally fiber-rich diets for which health benefits have been shown
Other NSP	Many types of constituents	Food additives. Minor components of the human diet. The amounts added to foods are known and regulated

FSG, free-sugar glucose; RAG, rapidly available glucose; SAG, slowly available glucose.

largely soluble and expected to have only a moderate effect on fecal bulk. Oats and rye contain a greater proportion of soluble NSP compared with wheat products, and the main fraction is a  $\beta$ -glucan, which is measured as soluble NSP glucose. This is associated with a greater effect on cholesterol metabolism, which is in agreement with the claims for oat products. Corn flakes provide an example of highly fiber-depleted breakfast cereal. Fruit and vegetables have high levels of soluble fiber, and the main fraction in these foods is pectin, which is measured as soluble NSP uronic acids. In general, cereal products contain more xylose than arabinose, while fruits and vegetables contain less xylose than arabinose, which is measured

mainly in the soluble fraction. The presence of the minor constituents, rhamnose and fucose, and the high values for uronic acids indicate a diet rich in fruits and vegetables. **Figure 1** illustrates the differences in NSP constituent sugars seen for cereals, fruit, and vegetables. When detailed information on the constituent sugars is not required, values for total, soluble, and insoluble dietary fiber may be obtained by the more rapid colorimetric endpoint procedure.

The detailed NSP analysis, which yields scientifically defensible values for physically and chemically identified constituents, is necessary for two major lines of approach to understanding the links between

dietary carbohydrates and health: (1) the correlation between dietary carbohydrate and disease as revealed from the analysis of epidemiological studies, and (2) the elucidation of the mechanisms that underlie the physiological importance of dietary carbohydrates for health. When used in food databanks and for food labeling, these data represent a reliable basis for

selecting the type of diet beneficial to health. The Englyst procedure for the measurement of NSP as a marker for dietary fiber in plant foods has been tested thoroughly in large international collaborative trials. Values for dietary fiber measured as NSP by this technique are used in the McCance and Widdowson UK food tables.

**Figure 1** NSP in different food types expressed as percentage monosaccharide present.

The purpose of labeling food with composition data is to provide the consumer with information on food quality. Which individual components appear on the label (e.g., energy, protein, fat, carbohydrate, sugar, starch, NSP, fiber) and how the values are obtained (by analysis by proscribed methods or by calculation) is decided by the legislators in each country or group of countries. There is no worldwide consensus on what material should be included in the term 'fiber' (or dietary fiber) and, hence, no worldwide agreement on a method for the measurement of fiber. Nutrition studies concerned with the qualitative and quantitative aspects of foodstuffs rely on specific definitions of food components and the availability of reliable methods of measurement. Identification of the NSP and the measurement procedure described here, with values for NSP constituent sugars, satisfy both requirements. The use of undefined terms, such as dietary fiber, and the use of nonspecific methodology satisfy neither of the criteria, and leads to the collection of uninterpretable and/or misleading data.

The argument is largely beyond the scope of this article but the reader is guided to relevant sources of information in the Further Reading and especially to the two WHO/FAO documents. If the information on the food label is to be meaningful for the consumer, it is important that the compositional values are accurate and, in a world of international trade, transcend geographical and language barriers. The Joint FAO/WHO Expert Consultations on Carbohydrates in Human Nutrition in 1998, concerning the analysis of dietary carbohydrates stated:

That the analysis and labelling of dietary carbohydrates, for whatever purpose, be based on the chemical divisions recommended. Additional groupings such as polyols, resistant starch, non-digestible oligosaccharides and dietary fibre can be used, provided the included components are clearly defined.

The measurement of plant cell-wall NSP as described here is in line with these recommendations, and provides values that can appear on the food label in many countries as fiber or dietary fiber. Any of the endpoint measures that can be used in the Englyst NSP procedure, GC, HPLC, or colorimetry, is suitable for food labeling and for quality control.

Studies designed (1) to examine the mechanisms underlying the links between diet and disease, and (2) to be the basis for preventive measures for the improvement and maintenance of public health, have an absolute requirement for specific definitions of food components and the availability of reliable methods of measurement. The approach used in the Englyst procedure for the measurement of the constituent sugars of the plant cell-wall NSP provides detailed analytical data that allow for sophisticated hypotheses to be erected and tested.

## Methods and Principles of Measurement

The Englyst procedure uses enzymatic and chemical methods to measure NSP. (For detailed working protocols, see Further Reading.) All starch is hydrolyzed enzymatically and NSP are measured as the sum of the constituent sugars released by acid hydrolysis. The sugars may be measured by GC or by HPLC to obtain values for individual monosaccharides, or a single value for total sugars may be obtained by colorimetry. Values may be obtained for total, soluble, and insoluble NSP, and a small modification allows cellulose to be measured separately.

The procedure as described here provides the following options:

1. GC procedure: measures NSP as the sum of neutral sugars obtained by GC and uronic acids measured separately.
2. HPLC procedure: measures NSP as the sum of neutral sugars and uronic acids.
3. Colorimetric procedure: measures NSP as reducing sugars.

The main procedural steps are

1. Dry/defat sample if necessary.
2. Disperse and hydrolyze starch enzymatically.
3. Precipitate NSP in acidified aqueous ethanol.
4. Disperse and hydrolyze NSP with sulfuric acid.
5. Measure released constituent sugars by colorimetry, GC, or HPLC.

Sample preparation includes freeze-drying and milling so that representative samples may be taken.

High-fat (>10%) samples are defatted with acetone. In order to disperse the starch completely, the sample is treated with dimethylsulfoxide, then buffered and the starch hydrolyzed with a mixture of pancreatic  $\alpha$ -amylase and pullulanase. After precipitation of the NSP with acidified ethanol, the supernatant is removed and discarded, or it may be used for the measurement of resistant short-chain carbohydrates (see **Table 1** and Further Reading). The precipitated NSP are washed with 80% ethanol to remove any free sugars and then dried with acetone. The dried, starch-free residue is treated with 72% sulfuric acid to disperse cellulose, followed by 2 mol l<sup>-1</sup> sulfuric acid for 1 h at 100°C to hydrolyze all the cell-wall polysaccharides to their constituent monosaccharides. When detailed information is required, the NSP sugars may be measured by GC or by HPLC, giving values for individual monosaccharides, or a single value may be obtained by colorimetry. In the GC procedure, the sugars are reduced to their alditols with alkaline sodium borohydride and acetylated with acetic anhydride in the presence of methylimidazole as catalyst. Conventional GC is used to measure the resulting alditol acetate derivatives of the neutral sugars. The uronic acid-containing polysaccharides are more difficult to hydrolyze and require treatment with concentrated acid at high temperature; for this reason, they are measured separately by colorimetry. In the HPLC assay, the hydrolysate is diluted, an internal standard is added, and the neutral sugars and uronic acids are measured directly by electrochemical detection.

Two kits are available from Englyst Carbohydrate to help ensure that accurate analytical results are obtained. The kit for the colorimetric procedure contains color reagent and a second kit contains a solution of allose as internal standard for the GC procedure. Both kits contain the required enzymes, sugar solutions, and reference materials and are rigorously tested in-house.

The four reference materials included in the kits may be used as part of a complete quality control procedure:

- Reference sample 1 (white flour). This sample is used to check the efficiency of the starch hydrolysis and washing steps when there is a small amount of NSP in the presence of a large amount of starch.
- Reference sample 2 (haricot bean). This sample contains all the constituent sugars of NSP and is used to check the efficiency of the starch hydrolysis and washing steps for samples that may cause handling problems, such as aggregation.

- Reference sample 3 (high-amylose starch resistant to  $\alpha$ -amylase). This sample is taken through the entire procedure for total NSP and is used to check the efficiency of the starch hydrolysis and washing steps.
- Reference sample 4 (cellulose). This sample is subjected to direct acid hydrolysis only and is used to check the acid hydrolysis steps.

## Method Validation

### Comparison of the Colorimetric, GC, and HPLC Assays

Three alternative endpoint techniques may be used to obtain values for NSP. The chromatographic procedures yield detailed information about the individual NSP constituent sugars. We have demonstrated that these chromatographic procedures give identical values for both neutral sugars and uronic acids. The colorimetric procedure has been shown in interlaboratory studies to give values for total, soluble, and insoluble NSP that are identical with the values obtained by the chromatographic procedures. The colorimetric assay is ideally suited for food labeling purposes, where a single value is required.

### International Collaborative Trials

The Englyst procedure has been the subject of a series of international collaborative trials organized by the UK Ministry of Agriculture, Fisheries and Food (MAFF). In the MAFF IV study, 37 laboratories from 11 countries compared the accuracy and precision of the Englyst GC and colorimetric procedures. This has culminated in the publication of the GC and the colorimetry techniques as MAFF Approved Methods.

## Certification of Reference Materials

As the result of a large international trial of methodology, following rigorous study of stability of the test materials, five EU Community Bureau of Reference certificated reference materials (CRMs) are available for use with the Englyst GC and colorimetry NSP procedures:

1. dried haricot bean powder, CRM 514;
2. dried carrot powder, CRM 515;
3. dried apple powder, CRM 516;
4. full-fat soya flour, CRM 517; and
5. dried powdered bran breakfast cereal, CRM 518.

These CRMs can be used to check the performance of the analytical method and as quality control of analytical measurements for nutritional labeling.

## Introduction

Carbon, as inorganic or organic species, is ubiquitous in all environmental regimes. Global carbon reservoirs of significance include land biota, soils, surface marine sediments, and the oceans. Of these, quantitatively the most important carbon reservoir at the earth's surface is the dissolved inorganic carbon (DIC) pool in the ocean, estimated to hold  $\sim 38\,000\text{ Gt C}$  ( $\text{Gt} = 10^{15}\text{ g}$ ). In contrast, the atmospheric pool of C as  $\text{CO}_2$  is estimated to hold  $\sim 750\text{ Gt}$ , compared to that estimated  $\sim 600\text{ Gt C}$  in preindustrial times. The changes in the chemical form (inorganic – see below – and organic C both in the dissolved and particulate phases) and environmental

reservoir quantities and fluxes between the reservoirs of C are linked to physical (atmospheric transport, diffusion, and solubility), chemical (acid/base equilibria), biological (respiration and photosynthesis), as well as anthropic processes (fossil fuel burning, forest destruction). Currently,  $\sim 4\%$  of the  $\text{CO}_2$  emitted into the atmosphere is of anthropogenic origin, this historic increase in  $\text{CO}_2$  inputs has led to the well-documented increase of  $\text{CO}_2$  atmospheric levels and the potential impacts on the global climate. The ocean is considered a significant sink for anthropogenically emitted atmospheric  $\text{CO}_2$ , taking up  $\sim 2.0 \pm 0.6\text{ Gt-C year}^{-1}$ ; the dynamics of this are mainly determined by the rate of transport of surface water that is rich in  $\text{CO}_2$  to depth. Therefore, to better quantitatively define the global C cycle and reservoirs, accurate and precise monitoring of the C concentrations in atmospheric, terrestrial, and marine samples is imperative.

These CRMs can be used to check the performance of the analytical method and as quality control of analytical measurements for nutritional labeling.

## Introduction

Carbon, as inorganic or organic species, is ubiquitous in all environmental regimes. Global carbon reservoirs of significance include land biota, soils, surface marine sediments, and the oceans. Of these, quantitatively the most important carbon reservoir at the earth's surface is the dissolved inorganic carbon (DIC) pool in the ocean, estimated to hold  $\sim 38\,000\text{ Gt C}$  ( $\text{Gt} = 10^{15}\text{ g}$ ). In contrast, the atmospheric pool of C as  $\text{CO}_2$  is estimated to hold  $\sim 750\text{ Gt}$ , compared to that estimated  $\sim 600\text{ Gt C}$  in preindustrial times. The changes in the chemical form (inorganic – see below – and organic C both in the dissolved and particulate phases) and environmental

reservoir quantities and fluxes between the reservoirs of C are linked to physical (atmospheric transport, diffusion, and solubility), chemical (acid/base equilibria), biological (respiration and photosynthesis), as well as anthropic processes (fossil fuel burning, forest destruction). Currently,  $\sim 4\%$  of the  $\text{CO}_2$  emitted into the atmosphere is of anthropogenic origin, this historic increase in  $\text{CO}_2$  inputs has led to the well-documented increase of  $\text{CO}_2$  atmospheric levels and the potential impacts on the global climate. The ocean is considered a significant sink for anthropogenically emitted atmospheric  $\text{CO}_2$ , taking up  $\sim 2.0 \pm 0.6\text{ Gt-C year}^{-1}$ ; the dynamics of this are mainly determined by the rate of transport of surface water that is rich in  $\text{CO}_2$  to depth. Therefore, to better quantitatively define the global C cycle and reservoirs, accurate and precise monitoring of the C concentrations in atmospheric, terrestrial, and marine samples is imperative.

Additionally, water, soil, urban and enclosed air quality may be defined by their inorganic C content (e.g., alkalinity, CO in air, carbonate content in soils), also requiring accurate/precise analytical techniques. This article will therefore critically discuss both direct and indirect analytical methods currently available for inorganic C analysis.

## Aquatic Systems

Inorganic C may exist in natural water systems in a number of different chemical forms. These are carbonate ( $\text{CO}_3^{2-}$ ), hydrogencarbonate ( $\text{HCO}_3^-$ ), and dissolved  $\text{CO}_2$  (free and hydrated form). In natural waters, the inorganic forms of carbon are derived from the chemical weathering of carbonate rocks, the decomposition of biotic material (respiration), and solvation of atmospheric  $\text{CO}_2$ . The dissolved inorganic C species distribution is a function of pH and is described by equations given below (i.e., the carbonate system):

The total inorganic carbon (TIC) in aqueous solution is the sum of the concentrations of all the species, such that:

$$\text{TIC} = C_T = [\text{CO}_3^{2-}] + [\text{HCO}_3^-] + [\text{H}_2\text{CO}_3] + [\text{CO}_2] \quad [2]$$

The relative concentrations (to TIC) of the different inorganic C species (defined as  $\alpha_0$ ,  $\alpha_1$ , and  $\alpha_2$ ) will be dependent upon the solution pH and acid dissociation constants, such that

$$\begin{aligned}[\text{H}_2\text{CO}_3^*]/C_T &= [\text{H}_3\text{O}^+]^2 / [\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2 \\ &= \alpha_0\end{aligned}\quad [3]$$

$$\begin{aligned}[\text{HCO}_3^-]/C_T &= K_1[\text{H}_3\text{O}^+] / [\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2 \\ &= \alpha_1\end{aligned}\quad [4]$$

$$\begin{aligned}[\text{CO}_3^{2-}]/C_T &= K_1K_2 / [\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2 \\ &= \alpha_2\end{aligned}\quad [5]$$

where

$$K_1 = [\text{H}_3\text{O}^+][\text{HCO}_3^-] / [\text{H}_2\text{CO}_3] \quad [6]$$

and

$$K_2 = [\text{H}_3\text{O}^+][\text{CO}_3^{2-}] / [\text{HCO}_3^-] \quad [7]$$

$$pK_1 = 6.3; \quad pK_2 = 10.3$$

The distribution of the various C species against pH is presented in **Figure 1**. It is clear from **Figure 1** that

**Figure 1** The distribution of dissolved inorganic carbonate species in aqueous solution as a function of pH.

in the pH range of the majority of natural waters systems (6.5–9), the  $\text{HCO}_3^-$  chemical form will be the most predominant. At around pH 10.5,  $\text{CO}_3^{2-}$  becomes the predominant form.

The carbonate system plays an important role in moderation of the chemistry of natural aquatic systems (e.g., acts a pH buffer in seawater), which, in turn, influences biotic and chemical activities. Inorganic C is also a major component of the global C cycle; its subsequent atmospheric/oceanic interaction plays a major role in atmospheric  $\text{CO}_2$  levels and hence global warming processes (see above). For example, an oceanic uptake of 40% will only correspond to an average change in DIC of  $1 \mu\text{mol l}^{-1}$ ; therefore, its accurate and precise determination and distribution is essential.

## Determination of Inorganic Carbon in Aquatic Systems

Samples collected for the subsequent analysis of TIC would typically require the use of polyethylene/borosilicate glass stoppered bottles (rinsed at least twice with the sample) to which is added a biocide (such as chloroform, mercuric chloride) and stored (avoiding a headspace) in the dark at  $4^\circ\text{C}$  (if immediate sample analysis is not possible). Airtight seals on the sample bottle should be ensured so that there is no loss or gain of  $\text{CO}_2$ . If TIC is to be determined by alkalinity titration, the pH of the sample should be noted upon sample collection.

Several approaches have been adopted to determine the TIC. Perhaps the most commonly applied is the indirect approach by determination of the total alkalinity via titrimetry, and then computation of the various inorganic C species assuming attainment of

chemical equilibria. The total alkalinity is defined as the number of moles of  $\text{H}^+$  equivalents to the excess of proton acceptors (bases formed from weak acids with a dissociation constant  $K < 10^{-4.5}$  at  $23^\circ\text{C}$ ) over proton donors (acids with  $K > 10^{-4.5}$ ) species in one kilogram of sample. Whereas the carbonate alkalinity (presented in eqn [3]) represents the contribution made to the alkalinity of inorganic C species only:

$$\begin{aligned} \text{Carbonate alkalinity} \\ = 2[\text{CO}_3^{2-}] + [\text{HCO}_3^-] + [\text{OH}^-] - [\text{H}^+] \quad [8] \end{aligned}$$

Generally, in freshwaters total alkalinity determinations are carried out using additions of strong acids (either  $\text{H}_2\text{SO}_4$  or  $\text{HCl}$  in the concentration ranges  $0.02\text{--}0.1\text{ mol l}^{-1}$ ) to an end point pH of  $\sim 4.2\text{--}5.1$ , using an appropriate indicator or potentiometer. For accurate analysis determination a two-point or multi-point Gran plot method may be employed.

The amount of acid added to reach the end point corresponds to the concentration of  $\text{CO}_3^{2-}$  and  $\text{HCO}_3^-$  in the sample. The TIC may, therefore, be calculated from alkalinity and pH using

$$[\text{Alkalinity}] = C_T(\alpha_1 + \alpha_2) + k_w/[\text{H}_3\text{O}^+] - [\text{H}_3\text{O}^+] \quad [9]$$

( $k_w$  being the ionization constant for water and  $[\text{H}_3\text{O}^+]$  is the proton concentration in water sample). Using this approach, good precision may be obtained ( $< 5\%$ ), assuming all the usual precautions are taken when carrying out the titration.

The titrimetry approach is subject to a number of possible interferences. For example, in aqueous samples that are enriched in particulate material (riverine, estuarine, sewage) filtration is recommended (typically through a  $0.45\text{ }\mu\text{m}$  membrane filter) to remove any particulate surfaces that might contribute to the solution alkalinity. In addition, aqueous samples that contain high concentrations of surfactants (e.g., industrial, sewage) may need longer pH electrode equilibration times during the alkalinity titrations.

It should, however, be remembered that there are aquatic systems where alkalinity is not solely due to the presence of carbonate species, e.g., seawater/aqueous solution derived from anthropic activities. For seawater therefore the alkalinity would be more accurately represented by eqn [10]:

$$\begin{aligned} \text{Seawater total alkalinity} \\ = 2[\text{CO}_3^{2-}] + [\text{HCO}_3^-] + [\text{B}(\text{OH})_4^-] + [\text{HPO}_4^-] \\ + [\text{H}_3\text{SiO}_4] + [\text{MgOH}] + [\text{OH}^-] - [\text{H}^+] \quad [10] \end{aligned}$$

To determine the total alkalinity in seawater, a similar method to that for freshwater samples may be employed, i.e., the sample could be titrated with  $\text{HCl}$  (containing background electrolytes maintaining a comparable ionic strength of seawater). The titration would be monitored using a glass electrode. Total alkalinity may then be calculated from the titrant volume plotted against the electrode potential using a modified Gran plot approach. However, TIC can only be related to alkalinity when the other contributing species concentrations are known. Therefore, a direct method is more preferable. Hence, for the direct determination of TIC in seawater, a  $\text{CO}_2$  coulometer is used. The technique requires the removal of  $\text{CO}_2$  from an acidified (phosphoric acid) seawater sample and the subsequent absorption of  $\text{CO}_2$  in a solution of ethanolamine. The weak acid is then titrated by a strong base, using thymolphthalein as the indicator. The equivalence point is evaluated photometrically ( $610\text{ nm}$ ). Accuracy of the technique is assessed using a sodium carbonate standard solution. The adopted technique performs with a high degree of precision ( $\pm 0.1\%$ ) and accuracy ( $\pm \mu\text{mol kg}^{-1}$ ). This approach was recently adopted for the determination of DIC in seawater for the JGOFS (Joint Global Ocean Flux Study) program.

Aqueous samples may in addition be determined for TIC directly by nondispersive infrared (NDIR) absorption spectrometry providing very good selectivity and sensitivity. Typically during a sample analysis, the dissolved inorganic C is converted to  $\text{CO}_2$  by sample acidification and purged to the sample cell of an NDIR spectrometer using an inert IR carrier gas. Calibration is achieved by using a standard sodium carbonate solution. Interferences may arise from gaseous species evolved into the carrier gas from the sample having overlapping absorption bands. This for natural water samples is most likely to arise from water vapor, which is therefore removed prior to  $\text{CO}_2$  detection.

Following detection, alkalinity may be expressed in a number of units including equivalent concentrations of calcium carbonate in units of  $\text{mg CaCO}_3$ ; micro/milliequivalents, or molarity. Freshwater alkalinity may range from less than  $-200$  to  $500\text{ meq l}^{-1}$ , whereas in seawater a more consistent concentration of  $\sim 2.35\text{ meq l}^{-1}$  is generally observed.

## Inorganic Carbon Species in Soils

TIC in soils predominantly derives from carbonate minerals such as calcite ( $\text{CaCO}_3$ ) and dolomite ( $\text{MgCO}_3$ ). TIC will also be impacted upon by soil's

biotic respiration processes, which in turn may alter the soil pH and hence nutrient availability and uptake. Collection and storage methods of soil samples are not as critical as those required for water and gaseous samples. Samples should be stored dried between 35°C and 38°C. TIC is essentially determined by the addition of acid to the soil sample, converting the inorganic C into gaseous CO<sub>2</sub> which may then be determined by an infrared gas analyzer or a carbon dioxide coulometer (see above; analysis of seawater). Alternatively, CO<sub>2</sub> may be absorbed and then precipitated as BaCO<sub>3</sub>, followed by back titration. Inorganic C in soils has also been achieved by analyzing the CO<sub>2</sub> by a modified pressure calcimeter method (with a detection limit of 0.17 g in organic C kg<sup>-1</sup>). In addition, TIC in soils may be determined using the Van Slyke method. In this method, the volume of CO<sub>2</sub> and air in a reaction vessel, containing the soil sample that has been acidified, is measured. The volume of air and CO<sub>2</sub> is also determined after being passed through a solution of NaOH, effectively removing the CO<sub>2</sub>. Measuring the residual air (at specific temperature and pressures) will allow the determination of the volume of CO<sub>2</sub> evolved from the acidified soil sample, and hence the TIC. Detection limits are ~0.01% (w/w) using this method.

## Determination of Inorganic Carbon in Gaseous Media

Inorganic C in the atmosphere may be present either associated with aerosol material (mainly crustal material, derived from physical weathering of soils and rocks) or as carbon monoxide/dioxide. In terms of human and environmental impacts, gaseous CO and CO<sub>2</sub> are of most importance. Both species have anthropogenic and natural sources. Natural sources include principally biotic processes (i.e., respiration, e.g., bacterial decomposition of plant material) whereas anthropogenic sources include combustion of fossil fuels via the internal combustion engine, power generation, and waste incineration. More recently, deforestation has contributed directly and indirectly to the atmospheric CO<sub>2</sub> levels. Atmospheric concentrations have increased from preindustrial revolution concentrations of ~280 ppmv (parts per million by volume) to ~370 ppmv (current day concentrations). The rapid enhancement of atmospheric CO<sub>2</sub> levels has, of course, led to the potential enhancement of the rate of global warming, leading to potential future climatic change. As a result of climate change, sea level rise, changes in the global oceanic circulation, and rainfall patterns are just a

number of potential environmental impacts. As a result, originating from the Kyoto agreement, nations have agreed to limit their CO<sub>2</sub> emissions. Therefore, there is a need to have accurate analytical systems to monitor ambient atmospheric CO<sub>2</sub> levels, emissions from industrial processes to ensure the efficiency of process control, as well as the effectiveness of environmental legislation and define trend in atmospheric CO<sub>2</sub> levels, to enable the better prediction of future climate change.

The impacts of CO<sub>2</sub> and CO on human health are also a consideration. CO exposure of levels down to 220 ppm may cause physiological effects such as the impairment of mental activity, headache, and irritability with enhanced levels in excess of 800 ppm causing loss of consciousness and even death if exposure is prolonged.

## Sample Collection

Any samples collected away from the analyzer are done so using a discrete sampler with exit and input ports. Air samples may be actively collected with a vacuum system – with a volume of air passed through the system typically being 10 times greater than that of the collection system. Alternatively, samples may be collected in an evacuated container. Continuous monitoring (long-term temporal environmental sampling or industrial process monitoring) should consist of an inert sampling probe located at minimal distance from the analyzer (to provide real-time data) and where high-temperature processes are being monitored and a cooling and dehumidifying system should be incorporated. Particle/corrosive gas removal systems may also be required for monitoring certain industrial processes. These are required to minimize spectral interferences by light scattering and degradation of the transport system and analytical instrumentation, respectively. In addition to sampling discrete air samples or continuously online, passive samplers may be employed.

## Detection of CO<sub>2</sub> and CO in Air

Detection of both gases may simply be carried out by injection of the sample into a GC (gas chromatograph) integrated with a detection system that might be one of the following: thermal conductivity detector, flame ionization detector (FID), or helium glow discharge ionization detector (DID). Precision of such measurements may range in the order of 2% (manual injection) down to 0.5% (direct gas

sampling). Using a TCD, detection limits are typically  $\sim 10 \text{ ng ml}^{-1}$ . Modifying the chromatographic parameters (such as the stationary phase chemical characteristics) may separate any interfering gases. The sensitivity of the detection system for CO may be enhanced (possibly lowering of the detection limits by an order of magnitude) by reacting hydrogen with CO in the presence of a catalyst (heated in Ni) to produce methane before FID detection. However, the methanization will add an extra stage in the analytical process and contamination of hydrogen with methane is often a problem.

Carbon dioxide may be further determined using an NDIR analyzer. The NDIR measures the absorption of IR radiation ( $4.26 \mu\text{m}$ ) due to the presence of  $\text{CO}_2$  traveling through the optical path of the detection system. Measurements are based on a comparison of ambient air- $\text{CO}_2$  mixing ratios in tanks of compressed reference gases. The analyzers operate in differential mode, with a 'zero' reference gas of  $\text{CO}_2$  mixing ratios 20–30 ppm below ambient  $\text{CO}_2$  levels. However, the NDIR is subject to interference by other gaseous species (having overlapping absorption bands) including water vapor, methane, and ethane. The application of the NDIR is the preferred approach for the determination of atmospheric  $\text{CO}_2$  in the atmosphere at remote regions. To lower water vapor interference sampled air is generally dried prior to the introduction into the gas analyzer. Accuracy of such systems are typically  $\pm 0.1 \text{ ppm}$ .

Carbon monoxide may be determined in the work place using direct reading monitors (sampling times of up to 8 h) and detection limits down to 1.6 ppmv (upper measurement limit 2000 ppm) and a precision of  $\sim 10\%$ . The system consists of a three-electrode diffusional electrochemical sensor incorporating a CO filter. A more sensitive approach is to incorporate a GC with a DID detection system. Helium is generally used as the carrier gas/ionized species. Passing the sample through a molecular sieve eliminates  $\text{CO}_2$  interference. The system may achieve detection limits of  $\sim 0.4 \text{ ppm}$ .

## Production of Cement

Portland cement is a complex mixture of compounds formed from the oxides of calcium (CaO), silicon (SiO<sub>2</sub>), aluminium (Al<sub>2</sub>O<sub>3</sub>), and iron (Fe<sub>2</sub>O<sub>3</sub>). In addition to these four main constituents, it also contains smaller amounts of magnesium oxide (MgO) and oxides of the alkali metals potassium (K<sub>2</sub>O) and sodium (Na<sub>2</sub>O). It is produced by heating together naturally occurring raw materials containing the required oxides in a kiln at ~1400–1500°C, which results in a product called clinker. The clinker is then ground together with gypsum (which controls setting) to a fine powder. Additional constituents such as granulated blast furnace slag, pulverized fuel ash (PFA), or limestone filler may be used. The grinding process and the addition of these constituents contribute to the different setting times and strength growth patterns of the range of cements needed to meet market requirements.

The source of CaO in the clinker is calcium carbonate either as chalk or limestone, and the SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, and Fe<sub>2</sub>O<sub>3</sub> are normally obtained from either clay or shale. The raw materials are quarried, crushed, and blended in the required proportion and the resulting powdered material (raw meal) is then fed into a rotating kiln. The raw meal passes through a burning zone in which the high temperature is generated by burning finely ground coal inside the kiln. The compounds formed can break down on cooling, and it is necessary to cool the resulting clinker rapidly to preserve the cementitious compounds that have been formed. As a final step in the process, the clinker is mixed and ground with a proportion of calcium sulfate to provide a product with the required setting and strength properties. The calcium sulfate can be naturally occurring gypsum, or come from an industrial by-product such as power station desulfurization waste. Other materials may be added either as ‘fillers’, e.g. raw meal, or as ‘extenders’, when substances that have some inherent cementitious characteristics are used, e.g. PFA or

**Table 1** Typical compositions of Portland cements

Oxide	OPC (wt. %)	WPC (wt. %)	SRPC (wt. %)
SiO <sub>2</sub>	20.7	22.5	20.5
Al <sub>2</sub> O <sub>3</sub>	5.75	4.50	3.75
Fe <sub>2</sub> O <sub>3</sub>	2.50	0.30	5.50
Mn <sub>2</sub> O <sub>3</sub>	0.05	0.03	0.05
TiO <sub>2</sub>	0.30	0.33	0.30
P <sub>2</sub> O <sub>5</sub>	0.15	0.17	0.15
CaO	64.0	67.5	64.5
MgO	1.00	0.35	0.75
SO <sub>3</sub>	2.75	2.50	2.20
K <sub>2</sub> O	0.60	0.10	0.40
Na <sub>2</sub> O	0.20	0.12	0.20
Free lime	2.0	2.5	1.0

Loss on ignition as CO<sub>2</sub> and H<sub>2</sub>O is 0.5–3.0 wt. %.

blast furnace slag. It is more common for these extenders to be added by the concrete makers rather than at the cement works.

The most commonly produced cement is Portland cement to British Standard BS 12, which represents ~90% of the market, which includes products such as rapid hardening and coarse ground cements, and white Portland cement (WPC). Other cements covered by other British Standards include sulfate resisting Portland cement (SRPC), Portland blast furnace cement, high slag blast furnace cement, and Portland PFA cement.

WPC is so-called because of its color. It is made from the purest chalk and kaolinite, and contains much less Fe<sub>2</sub>O<sub>3</sub> than the normal gray Portland cement. SRPC is produced for its resistance to sulfate attack, and has a higher Fe<sub>2</sub>O<sub>3</sub> content, often added to the raw meal as iron oxide. The other types named above contain a major (>5 wt. %) constituent. They are used for a variety of reasons, sometimes simply cost reduction, but often to exploit their particular properties. Standards and Codes of Practice regulate their use by specifying appropriate applications and minimum strength, and/or minimum cement content, of a concrete.

Typical compositions of three types of Portland cement are shown in Table 1. Although other oxides are present, it is the contents of CaO, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>, and their state of combination, that are of prime importance in the production of high quality Portland cement.

## Cementitious Compounds

The firing together of the calcareous and siliceous materials at 1400–1500°C produces a mixture of

four crystalline compounds. They are tricalcium silicate ( $3\text{CaO} \cdot \text{SiO}_2$ ), dicalcium silicate ( $2\text{CaO} \cdot \text{SiO}_2$ ), tricalcium aluminate ( $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ ), and an aluminoferrite phase which approximates to tetracalcium aluminoferrite ( $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ ). In practice, small quantities of other elements are also present in solid solution in these compounds, and in the cement industry they are known by the shortened names  $\text{C}_3\text{S}$  or alite,  $\text{C}_2\text{S}$  or belite,  $\text{C}_3\text{A}$  and  $\text{C}_4\text{AF}$ , respectively. Provided that the compositions of the raw materials are accurately known, and the correct amounts are blended together to make the raw meal, then all the  $\text{CaO}$  present will potentially react with one of the other oxides to form the above compounds. In practice, the reactions are never entirely complete and some unreacted 'free lime' will be present in the clinker. A high free lime content, for instance by incorrect formulation of the raw meal, can give rise to expansion and cracking in concrete. If an excess of siliceous material is present, this adversely affects the  $\text{C}_3\text{S}$  content of cement, and consequently decreases strength development at early ages.

## Control and Quality Parameters

The production of high-quality cement is a combination of control of the composition of the blended raw materials that are fed to the kiln, and quality checks on the composition of the resulting clinker and cement. Perhaps the single most important control parameter is the chemical composition of the raw meal, which in turn relies on a knowledge of the composition of the raw materials. If these two parameters are precisely controlled, and the kiln is operated in the required manner, then the composition of the clinker should be correct. In practice of course, its quality and that of the final product are regularly checked.

Although cement making employs and produces what is essentially a mixture of oxides, control of the process is monitored through the determination of a series of moduli which are derived from the concentrations of the oxides.

These moduli provide information which is more easily interpreted than the individual oxide contents, and yield key information leading to predictions on the chemical species in the final product.

The main modulus used to monitor the blending of the raw materials is called the lime saturation factor (LSF). This is a measure of the chemical balance between the calcareous and siliceous components. When there is complete balance the LSF has a value of 100%, and this theoretically leads to the

maximum possible proportion of the silica being combined as  $\text{C}_3\text{S}$ . The LSF is given by the expression (where compounds are expressed as wt.%)

$$\text{LSF} = \frac{[(\text{CaO}) - 0.7(\text{SO}_3)] \times 100\%}{[2.8(\text{SiO}_2) + 1.2(\text{Al}_2\text{O}_3) + 0.65(\text{Fe}_2\text{O}_3)]}$$

The  $\text{SO}_3$  content may not be appropriate for raw meal.

Since it is known that there is always some uncombined  $\text{CaO}$  in the clinker, another modulus is used which takes account of this 'free lime'. It is called the lime combination factor (LCF) and is given by the expression

$$\text{LCF} = \frac{[(\text{CaO}) - 0.7(\text{SO}_3) - (\text{free CaO})] \times 100\%}{[2.8(\text{SiO}_2) + 1.2(\text{Al}_2\text{O}_3) + 0.65(\text{Fe}_2\text{O}_3)]}$$

Two other moduli that are used allow the proportions of  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$ , and  $\text{C}_4\text{AF}$  to be predicted. These are the silica ratio and the alumina-iron ratio. They are expressed (as wt.%) as follows:

$$\text{silica ratio} = \frac{\text{SiO}_2}{\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3}$$

$$\text{alumina-iron ratio} = \frac{\text{Al}_2\text{O}_3}{\text{Fe}_2\text{O}_3}$$

## Bogue Calculations

Whilst the above moduli are used for online control of the process, the ultimate properties of the cement, such as setting time and strength, depend on the contents of the compounds  $\text{C}_3\text{S}$ ,  $\text{C}_2\text{S}$ ,  $\text{C}_3\text{A}$ , and  $\text{C}_4\text{AF}$  present in the clinker. These may either be arrived at by direct analytical means or alternatively, and more commonly, by using what are known as the Bogue calculations. These calculations use the contents of the four major oxides,  $\text{CaO}$ ,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ , to predict, with stated assumptions, the contents of the above compounds.

First, it is assumed that all the  $\text{Fe}_2\text{O}_3$  is present as  $\text{C}_4\text{AF}$ . Then from the  $\text{Fe}_2\text{O}_3$  content, and using stoichiometry, the  $\text{C}_4\text{AF}$  content is calculated. This calculation also yields the amounts of  $\text{CaO}$  and  $\text{Al}_2\text{O}_3$  required, and therefore by difference the amounts remaining for further compound formation.

The next assumption is that all the remaining  $\text{Al}_2\text{O}_3$  is present as  $\text{C}_3\text{A}$ . Again using stoichiometry the amount of  $\text{C}_3\text{A}$  can be calculated.

Some of the remaining  $\text{CaO}$  is present as 'free lime', and some is also present in the gypsum which is added. So assuming that all the  $\text{SO}_3$  is present as

$\text{CaSO}_4$ , then the  $\text{CaO}$  combined with the  $\text{SO}_3$  can be calculated.

Ignoring for the sake of simplicity the possible role of other minor constituents, the  $\text{CaO}$  remaining, after subtracting from the total  $\text{CaO}$  the amounts present as  $\text{C}_3\text{A}$ ,  $\text{C}_4\text{AF}$ , free lime, and gypsum, is combined with  $\text{SiO}_2$  as  $\text{C}_3\text{S}$  and  $\text{C}_2\text{S}$ .

To arrive at values for these two compounds, the amount of  $\text{CaO}$  required to convert the whole of the silica to  $\text{C}_2\text{S}$  is calculated, and then the remaining  $\text{CaO}$  is used to convert its equivalent of  $\text{C}_2\text{S}$  to  $\text{C}_3\text{S}$ . Thus the contents of the four compounds can be calculated from concentrations of  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{SiO}_2$ ,  $\text{SO}_3$ , and the free lime.

These calculations can be condensed into four equations (where compounds are expressed as wt.%):

$$\text{C}_3\text{S} = 4.07 \times (\text{CaO} - \text{free lime}) - 7.60 \times \text{SiO}_2 \\ - 6.72 \times \text{Al}_2\text{O}_3 - 1.43 \times \text{Fe}_2\text{O}_3 - 2.85 \times \text{SO}_3$$

$$\text{C}_2\text{S} = 2.87 \times \text{SiO}_2 - 0.7544 \times \text{C}_3\text{S}$$

$$\text{C}_3\text{A} = 2.65 \times \text{Al}_2\text{O}_3 - 1.69 \times \text{Fe}_2\text{O}_3$$

$$\text{C}_4\text{AF} = 3.04 \times \text{Fe}_2\text{O}_3$$

## Analytical Requirements

Cement production is a continuous process, with the blended raw meal entering the kiln at one end, and clinker emerging at the other to be mixed and ground with gypsum and optionally other fillers to produce the final product. This process continues 365 days a year, and close continuous analytical control must be maintained to ensure product quality. Since a large kiln is capable of producing 100–200 tons per hour, analysis must be rapid, whilst at the same time being both precise and accurate.

Table 2 shows the typical range for Portland cement, although in practice the range for an individual works would be much narrower.

## Analytical Methods

### Determination of $\text{CaO}$ , $\text{SiO}_2$ , $\text{Al}_2\text{O}_3$ , $\text{Fe}_2\text{O}_3$ , $\text{MgO}$ , $\text{SO}_3$ , $\text{K}_2\text{O}$ , and $\text{Na}_2\text{O}$ in Raw Materials, Raw Meal, Clinker, and Cement

Although chemical methods exist and are published in BS 4550 and EN 196, X-ray fluorescence analysis has become the standard industrial method for determining these eight oxides in raw materials, raw meal, clinker, and cement. It fulfills all the requirements for speed, precision, and accuracy and is also simple to use, such that control analysis can be

**Table 2** Composition ranges for Portland cement

Oxide	Concentration range (wt.%)
$\text{SiO}_2$	18.0–24.0
$\text{Al}_2\text{O}_3$	4.0–8.0
$\text{Fe}_2\text{O}_3$	1.5–4.5
$\text{Mn}_2\text{O}_3$	0.03–0.5
$\text{TiO}_2$	0.2–0.4
$\text{P}_2\text{O}_5$	0.05–0.3
$\text{CaO}$	62.0–66.0
$\text{MgO}$	0.7–4.0
$\text{SO}_3$	1.5–3.5
$\text{K}_2\text{O}$	0.1–1.5
$\text{Na}_2\text{O}$	0.1–0.9
Free lime	0.5–3.0
Loss on ignition	up to 3.0
Insoluble residue	up to 1.5

carried out by relatively inexperienced shift chemists on a 24 h per day basis.

Three types of X-ray fluorescence (XRF) spectrometers are available:

1. Wavelength-dispersive scanning XRF spectrophotometers.
2. Wavelength-dispersive multichannel XRF spectrophotometers.
3. Energy-dispersive XRF spectrophotometers.

All three types can be found in use in cement works control laboratories, but the preferred system is the multichannel type fitted with channels for the simultaneous determination of the eight elements Fe, Ca, K, S, Si, Al, Mg, and Na. Depending on the local geology, a channel for the determination of fluorine may be fitted if the limestone deposit is close to a source of fluorspar ( $\text{CaF}_2$ ). (The determination of fluorine is beyond the scope of an energy-dispersive XRF spectrometer.) At some works a channel is added to monitor the chlorine content of the clinker, which can be introduced from the fuel used to fire the kiln.

A suitable sample for an X-ray spectrometer is normally circular with a diameter of 30–40 mm and thickness about  $\sim 3$ –5 mm. For oxide materials a choice must be made between either direct pelletization of the powdered sample, or fusion of the sample with a suitable flux to form a glass bead of the appropriate dimensions. This choice rests between speed and accuracy, with direct pelletization being faster, and fusion potentially more accurate. As a general rule pelletization may be used for raw material and raw meal analysis, when the seams are reasonably pure, and when only two materials are employed (i.e., chalk/limestone and clay/shale).

When raw material composition is very variable, or when more than two are used as in SRPC, when iron ore and sand may be added, then fusion is the preferred technique.

### Sample Preparation by Direct Pelletization

For acceptable accuracy the particle size of the powdered sample for X-ray fluorescence should be less than the minimum path length of the X-radiation being measured in the analysis. For the elements present in cement this means a particle size of less than  $\sim 10\mu\text{m}$ . Since the particle size of the samples received for analysis is normally much greater than this, it is necessary to reduce it using a laboratory grinding mill. Those employed are usually of the 'swing mill' type, with a tungsten carbide barrel and grinding tools. Empirical grinding trials should be carried out to determine the optimum mill loading and grinding time to achieve a constant spectral line intensity for all the elements to be determined.

When suitable grinding parameters have been found, an aliquot of the ground powder is pressed into a pellet, normally of 40 mm diameter, up to 40 tons per square inch ( $6.2 \times 10^5$  kPa). The pellet may either be self-supporting or be made in an aluminum cup or metal ring to provide support. In order to produce a robust pellet, it may be necessary to use a chemical such as stearic acid or boric acid. Stearic acid can be introduced into the grinding barrel with the sample to be ground. It not only acts as a binder for the pellet, but also as a grinding aid to prevent agglomeration of the particles. Alternatively boric acid may be introduced into the bottom of the aluminum cup before pressing, with the ground powder placed on top. There are many different chemicals that can be used in this way, and for further information, reference should be made to texts on X-ray fluorescence. It should be said that failure to produce a robust pellet can lead to dust ingress to the spectrometer which can adversely affect its performance.

Manual, semiautomatic and fully automatic grinding mills and pelletizing presses are available, and there are machines that combine all these operations including cleaning the system between samples.

### Sample Preparation by Fusion

Elimination of the so-called particle size and mineralogical effects in X-ray spectrometry is the key to accuracy in the analysis of powdered materials. As previously stated, there are circumstances when acceptable accuracy can be achieved using pressed powder samples, but in many cases it is necessary to dissolve the sample in a suitable medium to destroy

the particles and render the sample homogeneous. Many cement works have now converted their XRF sample preparation to fusion having previously used pressed pellets, and the move in this direction seems to be inevitable as product quality requirements become more stringent, and sources of pure raw materials become less readily available.

The fusion medium in most common use is either sodium or lithium tetraborate ( $\text{Na}_2\text{B}_4\text{O}_7$  or  $\text{Li}_4\text{B}_2\text{O}_7$ ). Either may be used, but the sodium salt, whilst cheaper precludes the possibility of analyzing for sodium. It is also slightly deliquescent, so calibration standards must kept in a vacuum desiccator. Lithium tetraborate suffers from the disadvantage that its softening point is in the region of  $1200^\circ\text{C}$ , a temperature beyond the reach of some laboratory muffle furnaces. A mixture of lithium metaborate ( $\text{LiBO}_2$ ) and tetraborate in a ratio of 4:1 reduces softening point considerably, and is also reported to be more reactive with siliceous materials. This mixed flux is commercially available.

The fusion method involves dissolving an accurately known weight of the sample in an accurately known weight of the flux. The dissolution is usually carried out in a platinum alloy crucible, with the melt being cast into a bead in a preheated casting dish of the same alloy. A bead of suitable size for the spectrometer should weigh  $\sim 9$ – $10$  g, and flux to sample ratios in common use are 10:1 and 5:1. This means either 1 g or 1.5 g of sample and 10 g or 7.5 g of flux, respectively. The ratio 5:1 is preferable since not only does it dilute the sample to a lesser extent, thus achieving greater sensitivity of the X-ray measurement, but it is also less expensive on flux. Fusion can be carried out either in a laboratory muffle furnace, over a gas burner, or in one of the purpose-built commercially available fusion machines. Some of these machines are fully automatic, and include automatic weighing, multisample handling, and crucible-cleaning devices.

### Calibration

Calibration of the spectrometer is carried out by measuring samples of known composition to derive the parameters for the calculation of the concentration of each element in an unknown sample from the measured X-ray intensities. For the pressed powder method calibration samples covering a range of composition should be obtained from the normal production process. Since the aim of the process is to produce a constant composition, this can be difficult to achieve. The temptation to produce calibration samples by 'spiking' production samples to produce a range should be avoided, since this practice can lead

to gross inaccuracy. The powder method will only be successful when the calibration is carried out with samples that are from production and not synthetically produced. Powdered calibration samples can either be analyzed using wet chemical techniques, or by X-ray fluorescence spectrometry using the fusion method.

Calibration for the fusion method is achieved by the dissolution of carefully weighed aliquots of pure chemicals in the flux to provide a set of synthetic calibration beads to cover the required analytical range for each element. Where the pure oxide of any element is not available, then a compound which will convert to the oxide during fusion should be used. For example  $K_2CO_3$  can be used for  $K_2O$ . Normally five to ten beads should be sufficient, but care must be taken in the design of the set. Each individual bead should contain the equivalent of 100% (i.e., the sample weight for unknown samples, e.g., 1.5 g), and with the concentration range for each element well covered to avoid any possibility of extrapolation. Also the concentration series for one element should not follow the values for any other, either in an increasing or decreasing progression. This is important should the calculation of interelement correction factors be necessary.

The chosen calibration samples should be measured such that the counting statistical error for each element is small compared with other errors contained within the samples. These other errors are those associated with the chemical analysis of powdered samples and the weighing and other manipulations concerned with glass bead making. It is common practice to measure calibration samples for longer times than those used for the measurement of unknown samples. This helps to eliminate any unnecessary error in the calibration and therefore in the final analysis of unknowns.

Since the composition of the sample is variable, and therefore so is its mass absorption coefficient, it is sometimes necessary to carry out interelement corrections. The values of the correction factors can either be calculated from fundamental theory using commercially available software, or by multilinear regression analysis using the calibration samples. The former is preferred since the latter can force a mathematical fit to the data which bears no relation to X-ray theory.

**Determination of free lime** The determination of the uncombined CaO can be tackled in one of two ways. Historically this has been done using an acid-base titration after reaction of a weighed sample of clinker with ethylene glycol. The method is rapid and reliable and is still in common use. It is published in BS 4550 Part II.

More recently the industry has been investigating the use of an X-ray diffraction method, and this is now becoming accepted as an alternative to the chemical method. The advantages of instrumental techniques are clear in that they are much less prone to human error and by and large are simpler and less time-consuming. However, their accuracy must be proven, and the problems of preferred orientation and particle size effects have hindered such proof for the determination of free lime by X-ray diffraction. It should be borne in mind that CaO will react with moist air to form the hydroxide, the carbonate and the hydrogencarbonate. Analysis should be carried out rapidly once the sample has been taken, since the formation of these other chemical species will seriously affect the accuracy of the free lime determination, in particular by X-ray diffraction.

**Determination of the cementitious compounds  $C_3S$ ,  $C_2S$ ,  $C_3A$ , and  $C_4AF$**  As stated above, the common practice in cement works is to determine the contents of these compounds by using Bogue calculations together with the necessary assumptions. It should be stressed that the quantities of these compounds that are formed are a function, not only of the chemical composition, but also of the process itself, and the theoretical and actual quantities have been shown to be quite different in some cases. These inherent dangers are well recognized within the industry, and alternative methods are seen to exhibit inaccuracies of the same or greater magnitude.

Microscopy with point-counting can be used and, although it can be time-consuming, it is quite attractive in terms of its low capital cost. It also produces information on kiln performance not available from other methods.

The only other method that has gained any credence is X-ray diffraction. Whilst it is true that a full understanding of the reactions that take place, and the compounds that are formed in a cement kiln has resulted largely from X-ray diffraction studies, accurate quantitative analysis of cement clinker for the cementitious compounds has remained a research and development tool rather than a technique for industrial analysis. The accuracy of results achieved by quantitative X-ray diffraction analysis (QXDA) is limited by modifications to the diffracted beam intensities caused by substitution and solid solution. While the accuracy of Bogue calculations is limited by the soundness of the assumptions made, comparisons of results obtained using Bogue calculations and X-ray diffraction exhibit large discrepancies at times, but the decision as to which set of results is the more accurate remains difficult to take. Since the majority of cement works operate successfully using

Bogue calculations, it must be assumed that they are meaningful.

### Sample Preparation for QXDA

As in X-ray spectrometry, there is a need to reduce the particle size to below the level at which it will adversely affect the diffracted intensities. In practice, this means to about the 5  $\mu\text{m}$  level. Since the action of grinding the sample can at times induce phase changes, it is important that the grinding action is not too vigorous. This can be achieved by slow grinding in an agate ball mill with an inert liquid medium such as cyclohexane. This helps to keep the temperature down and also acts as a grinding aid.

Calibration samples and samples for analysis should be treated in the same way. The ground sample should be introduced into the sample holder of the diffractometer using the 'back-loading' method which reduces the effects of preferred orientation.

### Calibration

Calibration can be achieved by the use of synthetically prepared cement minerals, although these may be difficult to obtain. Since the composition of the sample is variable, and therefore so is its mass absorption coefficient, it is advisable to introduce an internal standard to both the calibration samples and samples for analysis. The elimination of the effect of variable absorption is achieved simply by taking all measured lines as a proportion of a line from the internal standard.

**Determination of loss on ignition and insoluble residue** Loss on ignition is determined by heating a weighed quantity of sample in a vitreous crucible at 950–1000°C in a muffle furnace.

Insoluble residue is determined by reacting the sample with hydrochloric acid, followed by solution in sodium carbonate and weighing the ignited insoluble residue.

Both methods are published in full in (BS) EN 196.

### Automation

X-ray fluorescence spectrometry has been established as the prime analytical technique for cement works control since the early 1970s. During the 20 years that have followed, X-ray spectrometers have been incorporated into complete control systems, which include sample transport from the sampling points to the works laboratory, sample preparation and transport into the spectrometer, analysis, calculation of control moduli, and generation and feedback of control signals to the plant to modify the process when necessary.

More recently, systems are being introduced that include an X-ray diffraction capability for the determination free lime content, and in some cases the  $\text{C}_3\text{S}$  (alite) content, of the clinker.

### Introduction

Analytical centrifugation is a method of studying the hydrodynamic properties of a molecule as it moves through a fluid medium. Hydrodynamic behavior depends on mass, density, and shape, so one can study these properties of a molecule by accelerating

a sample preparation in a centrifugal field. The analytical ultracentrifuge (AUC) contains a built-in optical system allowing one to observe the movement of a sample as it is spun in a centrifuge rotor. The centrifuge permits molecules to be studied in their native state, in solution, and has been useful in characterizing how proteins and other biological macromolecules bind to one another to form higher ordered structures. It has many other applications as well, including studies of polymers and colloids.

A great advantage of centrifugal studies is that the movement of particles in a centrifugal field can be accurately described by the laws of physics. Measurements can be made without comparisons to molecular standards. This makes it particularly useful for the study of proteins with properties that may differ from those of typically globular protein standards, such as glycoproteins, highly asymmetric molecules, and systems where association is reversible and concentration dependent. Analytical ultracentrifugation has also been referred to as solution interaction analysis to reflect its utility in the study of interacting systems.

The first AUC was built by T Svedberg, J B Nichols, and co-workers at Upsala in the 1920s. Svedberg began to develop the method, and used it to characterize proteins and other molecules in solution, demonstrating the individual character of biological macromolecules. His work led to the 1926 Nobel prize in Chemistry. The technology was commercialized by the Specialized Instrument Company (Spinco) in 1946, in the form of the Model E analytical ultracentrifuge. Now a part of Beckman Coulter, Inc., it is the sole manufacturer of AUC equipment today. Modern versions of AUC make use of a variety of optical systems and use an external computer for facilitated data acquisition and analysis.

## Theory

### Sedimentation

When a particle in a fluid medium is subjected to a centrifugal field it experiences three forces: sedimentation, buoyancy, and friction. The sedimentation force,  $F_s$ , is proportional to the particle mass,  $m$ , and to the centrifugal acceleration:

$$F_s = m\omega^2 r \quad [1]$$

where  $\omega$  is the rotational velocity and  $r$  is the distance from the center of rotation. The sedimentation force is opposed by a buoyant force,  $F_b$ , which is

proportional to the mass of the medium displaced by the particle:

$$F_b = -m\bar{v}\rho\omega^2 r \quad [2]$$

where  $\rho$  is the solvent density and  $\bar{v}$ , the partial specific volume, is the volume of fluid displaced per unit mass of solute. If the particle is less dense than the medium, the buoyant force will be greater than the sedimentation force, and the particle will float. Finally, the particle experiences a frictional resistance to its motion

$$F_f = -f\nu \quad [3]$$

where  $\nu$  is the particle velocity and  $f$  a frictional coefficient that depends upon the size and shape of the particle as well as the viscosity of the medium.

During centrifugation, these forces come quickly into balance and the particle reaches a terminal velocity,  $\nu$ , described by the Svedberg equation:

$$s = \frac{\nu}{\omega^2 r} = m(1 - \bar{v}\rho)/f \quad [4]$$

This equation defines a sedimentation coefficient,  $s$ , which may be thought of as the intrinsic speed of the particle and which depends on the molar mass and on the frictional coefficient. The sedimentation coefficient is expressed in Svedberg units, which equal  $10^{-13}$  s. Since it varies with temperature and solvent viscosity, it is often expressed as  $s_{20,w}$ , that is, the equivalent in 20°C water. The quantity  $m(1 - \bar{v}\rho)$  is called the buoyant molecular weight, and corresponds to the mass of the particle less than that of the displaced medium.

### Dynamic Distribution

In the case of macromolecules in a medium of lower density, centrifugation will cause the macromolecules to sediment, that is, to move through the medium and eventually to pellet on the outer wall of the sample compartment. At high centrifugal speeds, a boundary is observed at the top of the sample column, corresponding to the trailing edge of the solute distribution. In a sedimentation velocity experiment, a series of optical scans made during the pelleting of a sample is analyzed to determine its rate of movement and its shape (Figure 1).

By measuring the rate at which the boundary moves, an average sedimentation coefficient for the sample may be obtained. If multiple components are present, the boundary will broaden and may even resolve into discrete steps. However, diffusion will also cause the boundary to spread. Numerical or graphical methods are usually required to distinguish

**Figure 1** Formation and movement of the boundary in a sedimentation velocity experiment.

diffusional broadening from the presence of multiple species.

The evolution of the boundary is described by a partial differential equation, the Lamm equation

$$\frac{dc}{dt} = \frac{1}{r} \frac{d}{dr} \left[ rD \frac{dc}{dr} - s\omega^2 r^2 c \right] \quad [5]$$

This describes how the rate of change of a concentration distribution  $c(r, t)$  will be related to  $s$  and to the particle's diffusion coefficient,  $D$ .

Analysis of the sedimentation boundary and its displacement is used to study sample purity and molecular shape, and to describe systems such as polymers and associating macromolecules.

### Equilibrium Distribution

The boundary is a concentration gradient, and solutes will tend to diffuse against the gradient. At low centrifugal speeds, diffusional spreading will oppose sedimentation until eventually an equilibrium is achieved. Sedimentation equilibrium experiments lead to static exponential concentration distributions like the one shown in **Figure 2**.

At equilibrium, by definition, the concentration distribution no longer changes with time, and the Lamm equation is equal to zero. Then, an exponential solution may be found, of the form

$$c = c_k \exp \left[ \frac{\omega^2}{2RT} M(1 - \bar{v}\rho) (r^2 - r_k^2) \right] \quad [6]$$

where  $c_k$  is the concentration at a reference radial position  $k$ .

Both equilibrium and velocity studies are used to characterize a sample. Velocity runs are quick and provide an indication of the number of species present. Equilibrium runs give a more precise measurement of the masses of macromolecules and can be used to monitor their interactions. Together,

**Figure 2** Equilibrium distributions for a reversibly associating monomer–tetramer system. Individual species give rise to the lower traces. The upper trace is the sum of these, and is the one actually observed. (Courtesy of Beckman Coulter, Inc., used by permission.)

these complementary methods can be used to characterize the stoichiometry and kinetics of formation of large macromolecular complexes. Equilibrium distributions also provide a tool for determining the molecular weights of proteins with bound sugar or lipid moieties that are not amenable to measurement by techniques that rely on a comparison to protein standards.

### Nonideality

Although the theory of sedimentation as described holds for the near-ideal conditions encountered in most dilute biological preparations, refinements of the theory are required to deal with nonideal effects. Deviations from ideal behavior are caused by charge effects, hydration, or steric interference of molecules in concentrated solutions. Nonideal effects may result in an apparent concentration dependence of the sedimentation coefficient and an artificial sharpening of the boundary.

### Instrumentation

AUC instrumentation consists of a centrifugal drive unit, a rotor in which the sample is held, one or more optical systems to observe the sample, and a computer to acquire and to analyze the data.

Relative to preparative centrifugation, hardware requirements are particularly stringent with respect to rotor stability and temperature control. Rotor precession can lead to uncertainty in the measurement

of concentration and of radial position and must be held to an absolute minimum. Precise temperature determination is required for all data analysis calculations, since the sedimentation coefficient depends upon temperature. In addition, temperature instability may cause convective mixing of the sample. For this reason, the rotor is spun in a vacuum to eliminate frictional heating.

### Centrifuge and Rotor Systems

AUC systems are available commercially with several optical systems. The ProteomeLab XL-I<sup>TM</sup> model (Beckman Coulter, Inc.) is equipped with two optical detection systems. A Rayleigh interference system, driven by a 660 nm laser, measures concentration by monitoring refractivity, and a 190–800 nm xenon-lamp system measures sample absorbance. An XLA version, equipped with absorbance-optics only, is also available.

A 60 000 rpm four-position rotor and a 50 000 rpm eight-position rotor are supplied for these instruments. These rotors are made of titanium in order to withstand forces that may reach ~300 000 times the force of gravity. Normally, one sample position in the rotor is occupied by a counterbalance with ports for radial calibration, which is required to correct for the significant stretch exhibited by rotors at high speed. The other positions are occupied by cells in which the sample is held in a centerpiece between two windows. In the centerpiece are one or more sets of paired sample and reference cavities. For velocity experiments, a single pair of sector-shaped cavities is used. Each cavity wall coincides with a radius of the rotor – like slices of a pie – in order to minimize collision effects during sedimentation. Centerpieces for equilibrium experiments may have many sets of small cavities for multiple samples. Smaller cavities allow shorter runtimes, as a steady state is achieved more rapidly. These interchangeable centerpieces provide capacity to simultaneously process as many as 56 samples for equilibrium experiments, or seven samples for velocity runs. Sample volumes between 50 and a few hundred microliters are required, and the samples may be recovered after the run. A typical two-sector centerpiece and window assembly is shown in **Figure 3**.

There are also centerpiece designs that allow the sample to be added to a column of buffer dynamically, i.e., when the rotor is turning. In a band-forming centerpiece a small volume of sample is introduced to a buffer column through a capillary and migrates centrifugally in a narrow band. A synthetic boundary centerpiece allows two fluids to be layered while the rotor spins. This provides a sharp

**Figure 3** Sample cell, consisting of a centerpiece held between quartz windows (exploded view). The assembled cell is inserted into holes in the rotor and allows light to pass through the sample while the rotor spins. (Courtesy of Beckman Coulter, Inc., used by permission.)

interface in a strong centrifugal force field and is used for studies of diffusion.

### Optical Systems

The centerpiece is sealed by pressure between two windows made of quartz or of sapphire. Quartz windows are good for transmitting light in the far-ultraviolet (UV). Sapphire, which is less susceptible to stress deformation in high force fields, is preferred with interference optics.

Absorbance optics are useful for samples that absorb light in the available frequency range, and are frequently employed in the UV for studies of proteins and nucleic acids. The sample is illuminated by flashes from a wide-spectrum xenon lamp. Timing pulses derived from magnets embedded in the rotor are used to ensure that the lamp flashes when either the sample or reference sector is directly over a detector located beneath the rotor on the centrifuge chamber floor. A moving slit provides radial resolution by masking portions of the solution column. The measured absorbance is proportional to centerpiece thickness, i.e., path length, and to sample concentration. Three millimeter and 12 mm path length centerpieces are commercially available. These systems are capable of examining proteins at concentrations down to a few micrograms per milliliter or, in the case of

self-associating systems, for the determination of equilibrium constants as low as  $\sim 10^{-8} \text{ mol l}^{-1}$ .

In an interference optical system, coherent light from a laser is split into two beams. One is passed through the sample, and the other through the reference sector. The beams are then recombined and a pattern of fringes is created by constructive or destructive interference of the light waves. If one beam is slowed by higher refractivity of the sample, the fringe pattern will be shifted from a central reference position. This displacement is related to the sample concentration by

$$\Delta Y = c \cdot \frac{dn}{dc} \cdot L / \lambda \quad [7]$$

where  $\Delta Y$  is the pattern shift measured in fringes,  $dn/dc$  is the refractive increment of the macrosolute,  $L$  the path length (determined by the centerpiece thickness), and  $\lambda$  the wavelength. Interference systems are less sensitive than absorbance optics but are very precise, and cover a broad concentration range. Since all macromolecules cause refractive index changes, they may be used with any solute. Polysaccharides, for example, which do not absorb UV radiation, are amenable to study with this system. Interference optics are typically useful for protein concentrations in the range  $0.1\text{--}10 \text{ mg ml}^{-1}$ .

At the time of writing this article, a fluorescence optical system is under development by Aviv Biomedical Inc., and will be available as an accessory to the XL-I and XL-A instruments. Fluorescence optics provide very high sensitivity for studies of labeled or naturally fluorescent compounds. Test systems have proved useful with concentrations as low as  $800 \text{ pmol}$ , allowing determination of protein equilibrium constants below  $10^{-9} \text{ mol l}^{-1}$ . Studies with fluorescent tracers may also be used to characterize macromolecules at higher concentrations.

## Data Analysis

The analysis of AUC data has undergone a revolution in recent years because of the availability of powerful personal computers. Although graphical methods, which were the norm in the early days of the technique, may still be useful, the personal computer has fueled the development of several new and powerful analysis algorithms.

Desktop computational power has supported two significant trends in data analysis. Global analysis, the simultaneous processing of data from multiple experiments, has allowed characterization of molecular systems over broad ranges of concentration. And the use of iterative methods to arrive at approximate

solutions to the Lamm equation has increased precision significantly. In general, there will be several ways to analyze data from a given experiment, all of which offer comparable results.

## Equilibrium Experiment Analyses

Sedimentation equilibrium experiments may be used to determine the molecular weight of a solute. For molecules that self-associate or bind, the stoichiometry of the complex and a measure of the kinetics of association may also be determined.

Molecular weights are determined by solving the equilibrium form of the Lamm equation, generally by nonlinear least-squares fitting of the data to a presumptive model. For a monomeric solute (single ideal species), eqn [6] is a typical model. For associating systems, eqn [6] is extended by terms for each species present in the model. A monomer- $n$ -mer system is described by the model

$$c_{\text{total}} = c_{\text{k,monomer}} \exp \left[ \frac{w_2}{2RT} M(1 - \bar{v}\rho) (r^2 - r_k^2) \right] + c_{\text{k,nmer}} \exp \left[ \frac{w_2}{2RT} n M(1 - \bar{v}\rho) (r^2 - r_k^2) \right] \quad [8]$$

Stoichiometry can be determined from the mass of the largest species in a model that best fits the data. To study kinetics, an association constant,  $k_{\text{assoc}}$ , is defined such that

$$k_{\text{assoc}} = c_{n\text{-mer}} / (c_{\text{monomer}})^n \quad [9]$$

where  $c_{n\text{-mer}}$  is the concentration of a specific oligomer and  $c_{\text{monomer}}$  that of the monomer. Since all species are in thermodynamic equilibrium throughout the range of concentrations in the gradient,  $k_{\text{assoc}}$  may also be derived by solving the extended Lamm equation. Numerous software packages are available to perform this function. Foremost among these is a fitting algorithm called Nonlin, developed by Yphantis and colleagues at the University of Connecticut.

## Velocity Experiment Analyses

The primary goal of sedimentation velocity experiments is the determination of the sedimentation coefficient, which provides information about the mass and shape of sedimenting species. To this end, the analysis of velocity data seeks to determine (1) the rate of movement of the boundary and (2) whether the shape of the boundary indicates the presence of multiple species. Sample heterogeneity, or the presence of multiple species, will result in a broadening

of the boundary. A similar effect is produced by diffusion, so that it is necessary to distinguish the two.

Classical methods, such as the transport and second moment methods, provided only average sedimentation coefficients. Modern computer methods are more capable of distinguishing individual sample components, and generally return a sedimentation coefficient distribution that describes the range of particle sizes in the sample. Two forms of this distribution are common. In an integral sedimentation profile,  $G(s)$ , the percentage of material in the sample with sedimentation coefficient equal to or less than a particular value of  $s$  is plotted against  $s$ . In the absence of significant sample nonideality, these plots increase systematically from left to right, to a value of 100%. Individual species with specific sedimentation values will produce vertical limbs in these plots (Figure 4B). The differential sedimentation profile,  $g(s)$ , is simply the derivative of the integral distribution. Individual species appear as peaks in these plots, which are similar in appearance to chromatograms (see Figure 5).

**Extrapolation** A powerful approach making use of the integral distribution is the method of Van Holde and Weischet, a graphical method that evaluates the boundary to determine if all portions of it are moving at the same rate. The presence of multiple species will cause the upper portion of the boundary to appear to move more rapidly until, ideally, a step is eventually formed. This method takes advantage of the fact that diffusion is a much slower process than sedimentation by extrapolating the data to a time point at infinity in order to eliminate the effects of the former. The boundary is subdivided into a number of vertical segments and a sedimentation coefficient corresponding to the radial position of each segment is calculated. This process is repeated for boundaries observed at different times during the run, and the resulting  $s$  values are plotted against the inverse square root of the time. A straight line is fitted to the data for each segment and extrapolated to the axis, which represents infinite time (Figure 4A). A sample containing a single sedimenting species will result in a single intercept, whereas multiple species result in multiple intercepts. The data may be presented in the form of the extrapolation plot or else transformed into a plot of  $G(s)$  versus  $s$ .

**Time-derivative methods** Another approach to analyzing the sedimentation coefficient distribution is to generate the differential  $g(s)$  profile from the time derivative of the concentration profile,  $dc/dt$ . The derivative is approximated as the difference between paired scans acquired very rapidly. In practice,

**Figure 4** Van Holde–Weischet analysis for a sample mixture of two species. (A) Extrapolation plot. Each vertical array of points corresponds to a boundary obtained at the same time during the run, and straight lines are fitted to the points derived from similar portions of the boundary at different times. Extrapolation to the axis, or infinite time, eliminates the effects of diffusion. (B) Integral sedimentation coefficient, or  $G(s)$ , distribution representing the same data.

**Figure 5** Time derivative analysis for a sample mixture of two species. The rate of change of the concentration profile is approximated from the difference between scans, and transformed into a plot showing the distribution of sedimentation coefficients in the sample.

a series of scans is taken over a short interval and subtracted in pairs. The differences are then averaged to approximate  $dc/dt$ . Since faster-moving particles move a greater distance than slower ones during the finite time interval studied, a final transformation is required to convert  $dc/dt$  into  $g(s)$  (Figure 5). An advantage of this technique is that time invariant experimental noise, such as window scratches, is eliminated by the subtraction.

For molecules of similar shape, this approach may be further refined by correcting for diffusional spreading. A differential sedimentation coefficient distribution that incorporates a relationship between  $s$  and  $D$ , termed  $c(s)$ , is generated by a complex calculation. Exceptional sensitivity can be obtained in this manner.

**Direct boundary fitting** Sedimentation velocity data may also be analyzed by least-squares fitting to models based on the Lamm equation. Software packages exist which provide approximate analytical solutions to the equation and which run on desktop computers. Other software packages offer more precise finite element solutions to the equation but require substantial computational power.

### Introduction

Centrifugation is a mechanical process that utilizes a spinning medium to separate one or more components of a sample according to density or size. While gaseous or immiscible liquids can be separated by

centrifugation, the majority of applications involve sedimentation of solid particles in a liquid medium. Centrifugal separations may be classified as either analytical or preparative. In ‘analytical centrifugation’, the objective is to monitor particle sedimentation behavior in order to characterize particle properties, e.g., molecular weight, shape, and association. In ‘preparative centrifugation’, the objective is to separate and recover one or more components from a sample mix. Preparative centrifugation encompasses the vast majority of centrifugal applications.

While centrifugal techniques have been in use for at least a thousand years, the first recorded scientific study using a centrifuge did not appear until 1806, when Thomas Knight reported differences in the orientation of roots and stems of seedlings when placed in a rotating wheel. Some of the more significant developments since that time have included: the first commercial centrifuge, a hand-cranked cream separator, introduced in 1878 by the Swedish inventor, DeLaval; introduction of the analytical centrifuge for viewing particle sedimentation in 1923 by Theodor Svedberg; the isolation of subcellular components by centrifugal techniques in the 1940s; and the first use of a density-gradient medium by Edward Pickels in 1943. More recent advances have been characterized by significant improvements in materials and equipment and a broadening of applications.

Today, centrifuges are routinely used in a variety of disciplines including the medical, pharmaceutical, mineral, chemical, dairy, food, and agricultural industries. Available centrifuge designs and configurations seem almost as numerous as the applications themselves. An in-depth description of centrifuge designs and applications is beyond the scope of this treatise. Instead, this article will present the reader with an introduction to the theory of centrifugation, an overview of the various types of preparative centrifugal separations, and a description of some of the more common centrifuge and rotor designs along with their more common applications.

## Theory

### Sedimentation by Gravity

A particle suspended in a liquid medium of lesser density tends to sediment downward due to the 'gravity force',  $F_g$ :

$$F_g = mg = m \times 980 \text{ cm s}^{-2} \quad [1]$$

where  $m$  is the mass of the object and  $g$  is the gravitational-force constant.

For an object settling in a liquid or gaseous medium, there are two forces which oppose the gravitational force, the 'buoyancy force',  $F_b$  and the 'frictional force',  $F_f$ .

**Buoyancy force ( $F_b$ )** Archimedes showed that a particle suspended in a fluid experiences an upward force equivalent to the weight of the fluid being displaced:

$$F_b = m_M g = V_p \Delta_M g \quad [2]$$

where  $m_M$  is the mass of the fluid medium,  $V_p$  the volume of the particle (= volume of the displaced fluid), and  $\Delta_M$  the density of the displaced fluid.

**Frictional force ( $F_f$ )** In addition to the buoyancy force, the movement of a particle through a gaseous or fluid medium is hindered by the viscosity of the medium,  $\eta$  as described for a spherical particle by the Stokes' equation:

$$F_f = 6\pi\eta r_p (dx/dt) \quad [3]$$

where  $\eta$  is the medium viscosity in poise,  $P$  ( $\text{g cm}^{-1} \text{s}^{-1}$ ),  $r_p$  the radius of a spherical particle (cm), and  $(dx/dt)$  the velocity of the moving particle.

The frictional force increases as a function of particle velocity, eventually combining with the buoyancy force to precisely oppose the gravitational force. This condition is known as the limiting or 'terminal velocity'.

**Diffusion** Diffusion stems from random Brownian motion and results in the net movement of solute or suspended particles from regions of higher to regions of lower concentration. Thus, diffusion works in opposition to sedimentation which tends to concentrate particles.

While the precise impact of diffusion can be difficult to calculate for complex systems, it often suffices to know that the rate of diffusion is generally more pronounced for smaller particles, it increases with temperature, and its effects are lessened by higher centrifugal-force fields.

### Sedimentation in a Centrifugal Field

A particle moving in a circular path continuously experiences a 'centrifugal force',  $F_c$ , which may be expressed as

$$F_c = ma = m\omega^2 r \quad [4]$$

where  $m$  is the particle mass (g),  $a$  the acceleration ( $\text{cm s}^{-2}$ ),  $\omega$  the angular velocity ( $\text{radians s}^{-1} = 2\pi \text{ rpm}/60$ ), and  $r$  the radial distance from the axis of rotation to the particle (cm).

The centrifugal force acts to move particles away from the axis of rotation, while the buoyancy and frictional forces oppose this movement (**Figure 1**).

Centrifugal force can be related to the gravitational force,  $g$ , by the 'relative centrifugal force', (RCF), more commonly referred to as the  $g$  force:

$$\begin{aligned} \text{RCF} &= F_c/F_g = (m\omega^2 r)/(mg) = (\omega^2 r)/g \\ &= 1.19 \times 10^{-5} (\text{rpm})^2 r \end{aligned} \quad [5]$$

**Figure 1** Forces acting on a particle in a centrifugal field ( $F_b$ , buoyancy;  $F_f$ , frictional;  $F_c$ , centrifugal; and  $F_g$ , gravitational).

While RCF is unitless, it is frequently expressed in units of  $g$  to indicate the number of times that the force of the applied centrifugal field is greater than the force of gravity.

Analogous to gravity settling, a particle will attain a limiting or terminal velocity when the sum of the buoyancy and frictional forces equals the centrifugal force:

$$F_c = F_b + F_f \quad [6]$$

Assuming a spherical particle ( $4/3\pi r^3$ ), particle velocity can be calculated as

$$v = (d^2(\Delta_P - \Delta_M)\omega^2 r) / 18\eta \quad [7]$$

Equation [7] can be integrated to determine the time required for a particle to traverse a given radial distance from  $r_0$  to  $r_1$ :

$$t = [18\eta / (d^2(\Delta_P - \Delta_M)\omega^2)] \ln(r_1/r_0) \quad [8]$$

where  $r_0$  is the initial position of the particle and  $r_1$  the final position of the particle.

Equations [7] and [8] describe the impact of the more significant and controllable parameters that govern particle movement in a centrifuge. They reveal that, for a given particle density, the rate of sedimentation:

- Increases as a square function of rotor speed, e.g., doubling the speed will lessen the run time by a factor of four.

- Increases proportionally with distance from the axis of rotation.
- Is inversely related to the viscosity of the carrier medium.

### Sedimentation Coefficient

As shown, the sedimentation velocity,  $v$ , is proportional to  $\omega^2 r$ . This proportionality can be expressed in terms of the sedimentation coefficient,  $s$ , which is a measure of the sedimentation velocity per unit of centrifugal force. For a spherical particle,

$$s = (dx/dt) / (\omega^2 r) = 2r_p^2(\Delta_P - \Delta_M) / 9\eta \quad [9]$$

The sedimentation coefficient has the dimensions of time and is expressed in Svedberg units,  $S$ , equal to  $10^{-13}s$ . Its value is dependent on the mass and shape of the particle and on the sedimentation medium.

### Rotor Efficiency

The time required for a particle to traverse a rotor may be determined from the clearing- or  $k$ -factor, also known as the pelleting efficiency, with lower  $k$ -factors equating to shorter pelleting times. The  $k$ -factor is calculated at the maximum rated rotor speed and is a constant for a given rotor.  $k$ -Factors provide a convenient means of determining the minimum time required to pellet a particle and are thus, useful for comparing different rotors:

$$\begin{aligned} k &= \ln(r_{\max} - r_{\min}) \times 10^{13} / (3600\omega^2) \\ &= 2.53 \times 10^{11} \times \ln(r_{\max} - r_{\min}) / (\text{rpm})^2 \end{aligned} \quad [10]$$

where  $r_{\max}$  and  $r_{\min}$  are the maximum and minimum distances from the centrifugal axis, respectively.

When  $k$  is known (normally provided by manufacturer), the minimum run time required for particle pelleting may be calculated from the relation

$$t = k/s \quad [11]$$

where  $t$  is the time in hours required for pelleting and  $s$  is the sedimentation coefficient in Svedberg units.

### Deviation from Ideal Behavior

There are other, more difficult to characterize effects that lead to significant deviations from the settling velocity predicted by eqn [7]. The most common such effect occurs when the particles are nonspherical. Another example is for biological particles which interact with the medium via hydration, the extreme case being for osmotic particles which can result in drastic changes in particle density. Interparticle forces, e.g., charge or hydrophobic effects, may also impact sedimentation behavior.

## Types of Separations

Preparative centrifugal separations are often classified according to the phases of the media and the material to be purified, e.g., gas–gas, liquid–liquid, or liquid–solid. Gas-phase separations are very important in certain applications, e.g., uranium-isotope enrichment, but are highly specialized and not widely used. Liquid–liquid or even liquid–liquid–solid separations, on the other hand, are much more common. However, the majority of preparative separations involve the sedimentation of solid particles in a liquid medium.

Another way of classifying preparative separations is according to the method by which purified components are recovered. Three modes are used: (1) batch-mode, in which a sample mix is loaded, processed, and then recovered at the conclusion of the run by decanting the supernatant and scraping the pellet from the rotor wall; (2) semibatch mode, in which the sample mix is continuously fed to a spinning rotor as the supernatant is continuously discharged and the pellet is permitted to accumulate for postrun removal; and (3) continuous mode, in which the sample mixture is fed continuously, the supernatant is continuously discharged, and denser liquid or solid materials are either intermittently or continuously discharged during the run.

### Differential Sedimentation

As discussed, larger and/or denser particles will sediment more rapidly in a centrifugal-force field and thus, pellet onto the rotor wall faster than smaller or lighter particles. Most applications are based on this difference in behavior, referred to as differential sedimentation or ‘pelleting’. In a simple batch-mode pelleting separation, a sample mixture termed the homogenate (immiscible liquids or solid suspensions), is separated into two fractions as depicted in **Figure 2**. The unsedimented material is termed the ‘supernatant’ and the sedimented material is the ‘pellet’. This approach works well when the objective is to pellet all the solid particles or to clarify the liquid. However, obtaining high-purity separations by this approach can be difficult since the centrifugal field required to pellet larger or denser particles that are initially nearer the axis of rotation is capable of pelleting smaller or lighter particles that are initially closer to the outer wall (**Figure 2**). A more efficient one-step approach for isolating smaller or lighter particles is to layer the sample mixture on top of a preloaded cushion of dense medium then stopping the run before the lighter or smaller particles reach the rotor wall.

**Figure 2** Differential sedimentation or pelleting. (Courtesy of Beckman Coulter, Inc.)

### Density Gradient Centrifugation

A density gradient is a liquid medium that increases in density from the layers nearest the axis of rotation to those farthest away. This is achieved through variation in the concentration of an aqueous solute, or other gradient material, across the rotor. Density gradient centrifugation (DGC) compensates for some of the problems with separation efficiency encountered when using a homogeneous medium while permitting the simultaneous separation of multiple components from a single sample. DGC may be conducted as either rate-zonal or isopycnic separations.

**Rate-zonal separations** It can be used to separate particles of similar density according to size or to separate particles of different density and size as a function of their sedimentation coefficient,  $s$ . In its simplest form, the sample mixture is layered in a narrow band on top of a preloaded, homogeneous medium as shown in **Figure 3**.

The use of a density gradient instead of a homogeneous medium offers several advantages for rate-zonal separations. The steep gradient beneath the layered sample suppresses premature sedimentation as well as convection currents in the liquid column. Additionally, the continuous increase in density, and often accompanying increase in viscosity across the rotor, serves to slow the faster moving particles and provide better resolution in the sample component ‘bands’. Increasing-viscosity gradients also lessen diffusional effects, though this advantage may be offset by an increase in run time. Rate-zonal separations are well suited for mixtures of

**Figure 3** Rate-zonal separations in a swinging-bucket rotor. (A) Centrifuge tube filled with density gradient solution, (B) sample applied to top of gradient, and (C) under centrifugal force, particles move at different rates depending upon their mass. (Courtesy of Beckman Coulter, Inc.)

similar-density particles that exhibit two or more well-defined modes of size distribution.

**Isopycnic separations** They rely on differences in particle densities and are conducted in a density gradient. The density range of the gradient often spans the full range of particle densities so that particles never reach the rotor wall regardless of run time. Instead, particles sediment until they reach a position in which the density of the medium is equivalent to their own (Figure 4). Differences in particle size only affect their rate of movement, though this may ultimately dictate the required run time. When the range of particle densities exceeds the range of the density gradient, then both pelleting and isopycnic separation will occur as some particles fully traverse the rotor and pellet while others attain their isopycnic position and remain suspended.

**Gradient materials** The selection of an appropriate gradient material is an important consideration. As summarized by Griffith and Ridge, the ideal gradient material should:

- Span a density range sufficient to permit separation of the particles of interest.
- Be stable in solution.
- Be inert toward the fractionated materials.
- Exert the minimum osmotic effect, ionic strength, and pH.
- Be removable from the product.
- Be either inexpensive or easily recycled.
- Be sterilizable.

**Figure 4** Isopycnic separation with a self-generating gradient. (A) Uniform mixture of sample and gradient and (B) under centrifugal force, gradient redistributes and sample particles band at their isopycnic positions. (Courtesy of Beckman Coulter, Inc.)

On the other hand, the selected media should not generate a prohibitively high viscosity, interfere with the assay technique, be corrosive, or generate flammable or toxic aerosols.

Unfortunately, no single ideal gradient material exists, as each separation imposes its own set of requirements. The list of materials that have been used for gradient formation is extensive with examples of some commonly used materials listed in Table 1.

With respect to biological inertness and low viscosity, the most ideal aqueous gradient material is deuterium oxide ( $D_2O$ ). However,  $D_2O$  is expensive and has a relatively low maximum density ( $1.11 \text{ g cm}^{-3}$ ). Sucrose is a commonly used material due to its price, transparency, availability, and nontoxic nature. Densities to  $1.33 \text{ g cm}^{-3}$  can be achieved which is sufficient for separating most cells and intracellular organelles. More recently, Iodixanol (Optiprep<sup>TM</sup>) has gained in popularity. It has a density range similar to sucrose but a significantly lower viscosity and is iso-osmotic.

Salts are used to generate higher-density aqueous solutions. Cesium chloride ( $CsCl$ ) solutions, the most widely used of this class, can reach densities of  $\sim 1.9 \text{ g cm}^{-3}$  at saturation while providing low viscosity at lower concentrations.  $CsCl$  can be readily recovered and purified, but tends to be highly osmotic, corrosive, and expensive. The practitioner must be cautious not to overstress the rotor when using high-density salt solutions or when using salts that may precipitate, leading to catastrophic rotor failure.

For nonaqueous gradients, organic liquids such as toluene, methanol, or kerosene may be blended to

**Table 1** Physical properties of gradient materials in aqueous solutions at 20°C

	Maximum solution			20% w/w solution	
	Concentration (% w/w)	Density ( $\text{g cm}^{-3}$ )	Viscosity (cP)	Density ( $\text{g cm}^{-3}$ )	Viscosity (cP)
Sucrose	65	1.33	182	1.08	2

**Figure 5** Gradient shapes: (A) linear, (B) exponential, and (C) isokinetic.

attain gradient densities lower than  $1.0 \text{ g cm}^{-3}$ . Of these, methanol presents an additional advantage of being water soluble, thereby allowing gradients to be formed from a combination of the two. Halogenated liquids such as diiodomethane, bromoform, and tetrabromoethane can be used to prepare very dense solutions ( $>2.8 \text{ g cm}^{-3}$ ). Problems associated with flammability, toxicity, and deterioration of transfer lines and seals must be considered when using these materials.

**Gradient shape and formation** Gradient shape refers to the density profile across the tube or rotor as a function of gradient volume (Figure 5). Its choice is important as it governs the sedimentation rate as well as the terminal position in isopycnic runs.

Gradients may be classified as 'step' or 'continuous'. Step (discontinuous) gradients, are prepared by the step-wise addition of solutions of successively higher density to the rotor or tube. Step gradients have the advantages that they may be formed without the need for a gradient generator and may be easily 'tailored' to provide larger volumes of medium in the ranges that correspond to the density profile of the particles to be separated. For continuous gradients, the medium density varies in a continuous manner across the rotor or tube and may be further classified as linear, exponential, or isokinetic (Figures 5A–5C). 'Isokinetic' gradients are designed to produce a uniform sedimentation velocity throughout the

gradient by counterbalancing the increase in centrifugal force the particles experience as they traverse the gradient with an increase in medium density and viscosity. Simple linear sucrose gradients provide a near isokinetic gradient.

Numerous methods are used to form gradients. The simplest approach is to form the gradient *in situ*, i.e., self-generating, at high centrifugal speeds. However, higher rotor speeds and longer run times are often required for self-generating gradients and not all media or centrifugal equipment are amenable to this approach. Step gradients are also easily formed by simply pumping targeted volumes of successively denser solutions to the rotor. Inexpensive peristaltic pumps provide a convenient means to form step gradients. Gradient pumps are available to generate the targeted gradient curve shape including both mechanical and programmable electronic pumps that mix variable amounts of low- and high-density solutions.

Several approaches are used to analyze and/or fractionate the rotor effluent. The simplest is to split the gradient into fractions according to volume. Alternatively, the effluent may be routed through one or more in-line flow cells to monitor a selected gradient property, e.g., density, absorbance, refractive index, fluorescence, etc. Automated fractionators that switch collection vessels according to effluent volume or to feedback from an in-line detector are available.

### Continuous Centrifugation

In continuous separations, a sample mixture is continuously introduced to a spinning rotor as the clarified supernatant continuously exits. Continuous-feed centrifuges may be used for rate, pelleting, filtration, or isopycnic separations. They are best suited for applications in which large volumes and/or low-concentration samples must be processed, the particle sedimentation coefficient is high  $\geq 50 \text{ s}$ , or long acceleration/deceleration times are required.

In continuous centrifugation, the centrifugal force and flow rate must be controlled to provide sufficient time for solid or denser liquids to sediment before being carried out with the supernatant but not so long as to underutilize the rotor-throughput capacity. With information on liquid volume within the rotor and assuming laminar flow, the maximum flow rate can be determined from eqn [8]. Alternatively, if the rotor  $k$ -factor and the particle sedimentation coefficient are known, the minimum residence time required for pelleting can be calculated from eqn [11].

### Ultracentrifuges

Ultracentrifugation is an ill-defined term originally applied to analytical centrifuges and subsequently to units with rated speeds greater than  $\sim 25\,000$  rpm, regardless of the media or rotor design. Some manufacturers now reserve this term for centrifuges that operate at sufficient speeds to require a significant vacuum to reduce frictional drag and/or rotor heating.

### Filtration

Filtration is a mechanical means of separating solids from a liquid suspension via a porous medium or screen that permits the liquid to pass while retaining the solids. Centrifugal filtration is driven by the pressure exerted by a liquid medium and is opposed by the combined resistance of the porous filter and filter cake.

Centrifugal filtration is a complex process that is dependent on a number of parameters including liquid viscosity, cake thickness, centrifugal force, screen area, and importantly, the size and packing characteristics of the particles themselves. This technique is generally not amenable to broad generalizations and is, therefore, best approached on a case by case basis.

## Centrifugal Equipment

Centrifuges and rotors are commercially available in literally hundreds of shapes, sizes, and configurations. They range from small laboratory-scale units that can spin at speeds in excess of  $100\,000$  rpm delivering forces in excess of  $1\,000\,000g$ , to industrial-scale decanters that may continuously process up to  $300\,000\text{ l h}^{-1}$ . The primary rotor or centrifuge selection criteria must focus on the objective for conducting the separation. Parameters such as batch versus continuous; the required centrifugal force, purity; throughput; the number of components to be recovered; sample toxicity/corrosiveness; time; cost;

**Table 2** Strength data for commonly used rotor construction materials

Material	Density ( $\text{g cm}^{-3}$ )	Ultimate strength ( $\text{g cm}^{-3}$ )	Strength–density ratio
Aluminum	2.79	2159	774
Titanium	4.84	6088	1258
Steel	7.99	7915	991

available space; and noise tolerances should be considered.

Early rotors were often manufactured of steel or brass, but now, they are more commonly constructed of aluminum and titanium (Table 2). Newer composite materials have made tremendous gains in popularity, with plastics for small-scale applications, and stainless steel for industrial-scale units in common use. Though somewhat more expensive, titanium is particularly suitable as it has both a higher strength–density ratio and a high resistance to corrosion and erosion.

Centrifuge bottles and tubes are also constructed from a variety of materials including glass, stainless steel, and plastics, with polycarbonate being one of the more popular materials due to its transparency and strength. The choice of material is generally dictated by the required  $g$ -force and chemical compatibility with the sample and medium.

### Bottle Centrifuges

Bottle centrifuges consist of a motor-driven vertical spindle to which a horizontal rotor, machined with a number of sample positions is attached. Such units are normally equipped with a timer, tachometer, refrigeration system, and manual or automatic braking. Bottle centrifuges are usually smaller, bench-top units but are also available as larger, free-standing units.

Bottle-centrifuge rotors are classified as swinging bucket, fixed-angle, and vertical (Figure 6). In the ‘swinging-bucket’ design, the bottles are in a vertical position at rest but swing outward to a horizontal orientation as the rotor speed increases. The centrifugal force is applied along the length of the tube providing the best resolution for rate-zonal separations. ‘Fixed-angle’ rotors are loaded and operated with the tube remaining at a fixed angle both at rest and while spinning. This angle is typically  $20$ – $45^\circ$  from vertical, though ‘near-vertical’ rotors are less than  $10^\circ$  from vertical. The fixed-angle design provides a shorter path length with a corresponding reduction in run time. During the run, particles aggregate on the outer wall of the tube and slide down the tube wall to form a pellet in the bottom. Fixed-angle rotors provide the highest available force

**Figure 6** Particle separation in swinging bucket, fixed angle, and vertical tube rotors. (Courtesy of Beckman Coulter, Inc.)

fields. ‘Vertical’ rotors can be considered as an extension of fixed-angle rotors in which the angle of repose is  $0^\circ$  from vertical. In this design, the maximum path length is equal to tube diameter, thereby providing the lowest  $k$ -factors for a given tube. Vertical tube rotors are often used for isopycnic banding where short run times are desired. Density gradients will reorient during the acceleration and deceleration of a fixed-angle or vertical rotor, such that the gradient is vertical (aligned with gravity) while the rotor is at rest, and horizontal (aligned with the centrifugal field) while at speed.

### Zonal Rotors

Zonal rotors are bowls or cylindrical cavities equipped with a central core and attached vanes

or septa that divide the rotor into four or more sector-shaped compartments. Zonal rotors provide larger internal volumes for a given radius, minimal wall effects, and maximum particle and gradient resolution.

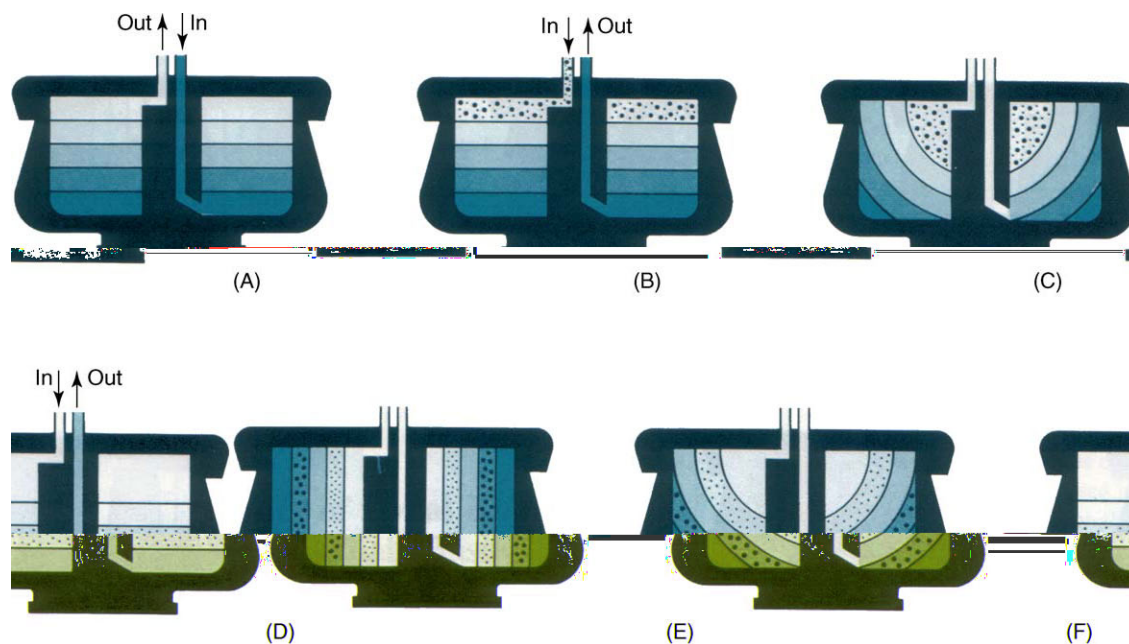

Zonal centrifuges can be operated in batch, semibatch, or continuous modes and may be loaded and unloaded with the rotor stopped (‘static or reorienting’) or spinning (‘dynamic or rotating seal’). In static loading, the gradient is loaded with the rotor at rest, the rotor slowly accelerated to permit the gradient to reorient from a horizontal to a vertical configuration, and then slowly decelerated back to rest for postrun unloading (Figure 7). The advantages of the static-loading technique are simplicity and the avoidance of rotating seals that may leak or fail during loading/unloading. The major disadvantage is

the tendency of the gradient to swirl as it reorients leading to a loss in resolution.

Dynamic loading and unloading is conducted as the rotor spins (Figure 8). The gradient is pumped

through a rotating seal in the center of the rotor lid to the outer wall of the rotor via passages machined into the rotor core. Lighter-density solutions are loaded first, forming a vertical layer which is

**Figure 7** Static loading and unloading of a zonal rotor with a reorienting gradient core. (A) Gradient loaded, light end first, with rotor at rest; (B) sample solution layered on top of gradient; (C) Rotor accelerated, layers reoriented under centrifugal force; (D) layers vertical, particles separated with rotor at speed; (E) rotor decelerated, layers reoriented; (F) static unloading, contents displaced with air pressure, heavy end first. (Courtesy of Beckman Coulter, Inc.)

**Figure 8** Dynamic loading and unloading of a zonal rotor. (A) Gradient loaded with rotor spinning at 2000 rpm, (B) sample injected at 2000 rpm, followed by injection of overlay, (C) particles separated with rotor at speed, and (D) contents unloaded by introducing dense solution at rotor edge, displacing fractions at center. (Courtesy of Beckman Coulter, Inc.)

displaced inward by the ensuing denser solutions. The rotor is unloaded by routing a high-density immiscible liquid to the outer wall forcing the gradient from the rotor, lighter fractions first (center unloading) or by pumping a light liquid to the center, displacing the heavier fractions first (edge unloading). While more cumbersome, dynamic loading generally provides better resolution than static loading/unloading.

### Continuous Centrifuges

**Figure 9** shows the major industrial applications of continuous centrifuges.

**Disk centrifuges** Disk centrifuges operate on the principle of differential sedimentation and are used for two-phase (liquid–solid or liquid–liquid) and three-phase (liquid–liquid–solid) separations. Disk centrifuges are essentially a rotating bowl equipped with an internal set of conical settling plates which

serve to decrease the sedimentation path length and increase the sedimentation surface area, i.e., capacity factor (**Figure 10**). Denser materials sediment onto and slide across the plate surfaces before accumulating on the bowl wall. These are highly efficient units with some industrial-scale units generating forces of 10 000g and capable of pelleting particles as small as 0.1  $\mu\text{m}$  diameter.

Three variations of disk centrifuges, distinguished by their solids-handling capability, are commonly used: solids-retaining, intermittent solids-ejecting, and continuous solids-ejecting (**Figure 10**). Solids-retaining designs (**Figure 10A**) are appropriate for liquid–solid or liquid–liquid separations where the solids content is less than  $\sim 1\%$  by volume. Common applications of solids-retaining disk centrifuges include separation of cream from milk, organic waste from water, purification of lubricating oils, or removal of water and solids from jet fuel.

Clarification: Separate suspended particles from a liquid

Purification: Separate immiscible liquids (even with solids present)

Dewatering: Concentrate a slurry

Classification: To split a suspension into two streams with different particle size distributions

Washing: Countercurrent washing or dissolving of impurities in suspended, crystallized or amorphous solids

Extraction: To mix a liquid containing a mineral or extract with a liquid agent, and then separate out the agent, which contains the extract or mineral, from the original liquid

design to process feed streams with low solids content. One configuration, designed for recovery of two immiscible liquids and a solids product, is shown in **Figure 11**. Due to their high speed and short settling path, tubular centrifuges are well suited for the pelleting of ultrafine particles, liquid clarification, and difficult to separate immiscible liquids, particularly when the objective is efficient recovery of high-value products. Industrial models are available with throughput rates to  $250 \text{ m}^3 \text{ h}^{-1}$  and forces ranging to  $20\,000g$  while laboratory models are available with throughput rates to  $150 \text{ l h}^{-1}$  and centrifugal forces ranging to  $62\,000g$ . Typical applications include recovery of *Escherichia coli* cells and flu viruses, blood fractionation, and deinking.

**Continuous zonal rotors** These rotors are similar to those designed for batch separation but with a larger diameter core providing a different flow pattern as illustrated in **Figure 12**. These rotors are best suited for low-concentration, high-volume samples. Applications include purification of viruses from tissue-culture media, harvesting bacteria, or separating fine-clay particles from water.

**Elutriation rotors** Elutriation or counterstreaming is a batch technique used to separate particles with

differing sedimentation rates (rate separation). Rotors with conical- or funnel-shaped cavities are used with the small end positioned farthest from the axis of rotation (**Figure 13**). The sample mixture is introduced at a constant rate to the small end of a pre-filled, spinning cavity. As the particles migrate inward toward the larger-diameter end of the cavity, they experience a decreasing centrifugal force due to the shorter radius of rotation and a decreasing frictional drag due to the decrease in the velocity of the counterflowing medium. As these forces are balanced, the particles will classify according to size. Particles of increasing size may then be collected by increasing the flow rate or by decreasing the rotor speed. Elutriation rotors provide high cell viability by operating at low centrifugal fields and permitting the separation to be conducted in any compatible medium. A common application is the isolation of specific mammalian cell types.

### Centrifugal Filtration Equipment

Filtration centrifuges are used for the separation of solids from liquid slurries, chiefly in industrial applications, and are usually characterized in terms of the final moisture content, drainage time, and centrifugal force. They are most useful for high-volume

processing of fast draining solids. Three of the more common designs are batch/semibatch basket centrifuges, and continuous push-type, and continuous conical centrifuges. Applications for continuous centrifugal filters include dewatering of crystalline solids, extraction of solids from fruit and vegetable pulps, and dewatering of coal fines.

## Introduction

The term ‘ceramic’ covers a wide range of materials, which makes it an interesting area of activity for the inorganic analyst. The range of matrices is described with reference to problems in preparation for analysis. Various methods of analysis are described and compared with respect to cost, general applicability, sensitivity, and accuracy. As might be expected, this article is primarily about bulk analysis, but speciation, surface analysis, and microstructural analysis are becoming more critical these days.

## Types of Ceramic Material

Ceramic materials are produced by heat treatment of minerals or mixtures of minerals, and the matrices have much in common with geological samples. For this reason, methods established for the analysis

of ceramic samples may also be applied to rocks, soils, ores and minerals as well as refractories, white-ware, glass, enamels, and cement. Ceramic materials may be divided into four industrial types as follows:

1. *Whitewares* (tiles, tableware, sanitaryware). These are traditional fired and unfired bodies, glazes, raw materials such as china clay, talc, bone or feldspar, and intermediates such as frits, slips, glazes, and colors.
2. *Building materials*. Bricks, breezeblock, cement, glass, concrete, tiles, clays, limestone, and additives such as stains and barium carbonate.
3. *Refractories*. Aluminosilicates, silica and aluminous material, basic materials such as magnesite, chrome-bearing materials such as magnesia-chrome bricks, zirconia-bearing materials, and silicon carbide. There are also raw materials such as fireclay, ferrosilicon, and graphite.
4. *Industrial or engineering ceramics*. This class includes a wide range of finished products and raw materials for biological, military, electronic, automotive, aerospace, and high-temperature uses. Typical materials include alumina, zirconia, titanate, silicon carbide and nitride, SiALON, and mixtures of rare earths.

## Introduction

The term ‘ceramic’ covers a wide range of materials, which makes it an interesting area of activity for the inorganic analyst. The range of matrices is described with reference to problems in preparation for analysis. Various methods of analysis are described and compared with respect to cost, general applicability, sensitivity, and accuracy. As might be expected, this article is primarily about bulk analysis, but speciation, surface analysis, and microstructural analysis are becoming more critical these days.

## Types of Ceramic Material

Ceramic materials are produced by heat treatment of minerals or mixtures of minerals, and the matrices have much in common with geological samples. For this reason, methods established for the analysis

of ceramic samples may also be applied to rocks, soils, ores and minerals as well as refractories, white-ware, glass, enamels, and cement. Ceramic materials may be divided into four industrial types as follows:

1. *Whitewares* (tiles, tableware, sanitaryware). These are traditional fired and unfired bodies, glazes, raw materials such as china clay, talc, bone or feldspar, and intermediates such as frits, slips, glazes, and colors.
2. *Building materials*. Bricks, breezeblock, cement, glass, concrete, tiles, clays, limestone, and additives such as stains and barium carbonate.
3. *Refractories*. Aluminosilicates, silica and aluminous material, basic materials such as magnesite, chrome-bearing materials such as magnesia-chrome bricks, zirconia-bearing materials, and silicon carbide. There are also raw materials such as fireclay, ferrosilicon, and graphite.
4. *Industrial or engineering ceramics*. This class includes a wide range of finished products and raw materials for biological, military, electronic, automotive, aerospace, and high-temperature uses. Typical materials include alumina, zirconia, titanate, silicon carbide and nitride, SiALON, and mixtures of rare earths.

The initial problem with ceramics lies in the fact that they have been designed to be resistant to wear, heat, and chemical attack, so that there are major difficulties in breaking them down or bringing them into solution. The other problem is that quite often there are two or more major constituents to determine. Materials discussed in this section can be regrouped in terms of difficulty of sample preparation.

(a) *High silica*. Samples are amenable to hydrofluoric acid attack, followed by analysis of the fused residue.

(b) *Silica/alumina*. Substances that contain silica and/or alumina as the major constituent. They generally require fusion for total decomposition.

(c) *Silicates*. These are effectively a variant of silica/alumina with another major element, and include talc, calcium silicates, cement, bone china, bone ash, and zircon. They are treated as silica/alumina, with lesser or greater difficulty in fusion and dissolution.

(d) *Basic*. Magnesite, limestone, and dolomite, which are decomposed by acid, usually with a fusion of the residue. Strontium and barium oxide also fall into this class but precipitation of sulfates is a problem.

(e) *Oxide*. Zirconia, titania, and other metal oxides that are usually difficult to decompose, whereas transition metal oxides (e.g.,  $\text{Fe}_2\text{O}_3$  and  $\text{MnO}$ ) are easier to decompose.

(f) *Reduced materials*. These include silicon carbide and nitride, SiAlON, silicon, graphite, and ferroalloys that require special methods for dissolution and speciation.

(g) *Complex materials*. These include some special ceramics, chrome-bearing refractories, colors, and enamels, where the presence of many minor and major constituents, especially rare earths, presents problems in analytical procedures. Decomposition procedures can fall into any of the six categories above. Ceramic materials also require analysis when added to composite matrices together with paint, plastic, rubber, metal, and cement.

## Sample Reduction and Communication

Obtaining a representative sample, which is not significantly contaminated with any of the elements to be determined, is an essential and vital part of ceramic analysis. However sophisticated the analytical procedures used, their results are worthless if sampling is not carried out properly. Many samples submitted for ceramic analysis are relatively small quantities of powder or small pieces that require

minimal grinding. Other samples, however, may be submitted in quantities of several kilograms in such forms as large bricks, broken rock, or wet clay.

Wet samples first require drying, possibly at temperatures as low as  $30^\circ\text{C}$ . Bulk samples are jaw crushed to  $\sim 4\text{ mm}$  and then subdivided by coning and quartering or by use of a riffle or mechanical sample divider to obtain a representative sample of 50–200 g for fine grinding.

As most analysis is by X-ray fluorescence (XRF) spectrometry and other instrumental methods, fine grinding is usually carried out in a tungsten carbide vial on a swing mill. The grinding parameters are set to produce a sample that would pass a  $125\text{ }\mu\text{m}$  sieve. Unless specified in a standard method, the sample is not actually sieved. For wet-chemical analysis, an agate pestle and mortar is to be preferred, but for hard materials of low silica content two samples are prepared: one in an iron percussion mortar, and another in an alumina mortar for subsequent iron determination. Tungsten carbide is unsuitable for 'wet' analysis as tungsten interferes with many of the determinations. For trace analysis, agate or boron carbide mortars are preferable but have to be used only for trace analysis to avoid surface contamination.

## Loss on Ignition

The determination of loss on ignition is a standard and is generally carried out at  $1025^\circ\text{C}$  on the dried  $110^\circ\text{C}$  sample.

Some samples require special procedures. Clays high in carbon such as brick or ball clay need a slower more careful pre-ignition to avoid silicon carbide (SiC) formation. Other materials require different temperatures. Bone ash requires ignition at  $1200^\circ\text{C}$ , fluorspar  $500^\circ\text{C}$ , glasses  $550^\circ\text{C}$ , plaster (gypsum)  $600^\circ\text{C}$  on an undried sample, and high-cobalt samples  $700^\circ\text{C}$ . Ferroalloys are not normally ignited, while glazes are heated over a burner at softening point. Silicon carbide, silicon nitride, silicon oxynitride, and SiAlON are ignited using a programmable furnace that allows slow burnout of carbon followed by a dwell at  $750^\circ\text{C}$ . In a proper full analysis, differential thermal analysis and thermogravimetric analysis (DTA/TGA) should be run both in air and argon atmospheres.

## Conventional Wet-Chemical Analysis

Wet-chemical analysis has largely been superseded by XRF analysis (with ICP for  $\text{Li}_2\text{O}$  and  $\text{B}_2\text{O}_3$ ) in all major ceramic laboratories. Some small laboratories cannot afford expensive capital equipment and continue to use wet methods, sometimes combined with

atomic absorption spectroscopy (AAS). Currently these methods are being revised within ISO rather than CEN as most European laboratories will not use them. Within ISO, wet methods are currently being brought up to date for silica–aluminosilicates–alumina (NP21587), limestone and dolomite (ISO10058), zircon and zirconia (based on JIS2012), and chrome-bearing samples (based on JIS2212). These procedures also allow the use of inductively coupled plasma (ICP) for some determinations.

The majority of wet-chemical analysis is for the silica–aluminosilicate–alumina range, and this is used to illustrate the methods used. The oxides determined are the normal eight (those of silicon, titanium, aluminum, iron, calcium, magnesium, potassium, and sodium). In ceramics, it is traditional to refer to the elements as their oxides. For the analyst, this has the advantage of providing an analytical total to cross-check the accuracy of the analysis.

The procedure for the determination of the alkalis ( $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ , and  $\text{Li}_2\text{O}$ ) is effectively identical for all classes of material in that ~0.25 g of sample is decomposed with hydrofluoric acid together with dilute nitric and sulfuric acids in a platinum dish on a sand bath. The residue is dissolved in dilute nitric acid and alkalis determined directly on the solution by flame photometry or flame atomic absorption spectroscopy (FAAS) in emission mode. Cesium and aluminum sulfate buffers are added to aliquots for the flame photometric determination of sodium and potassium.

For classes (a)–(c) and for SiC, the main analysis solution is prepared via a low flux/sample ratio fusion or, in the case of alumina, a sinter at 1200°C. The flux used is a mixture of fusion mixture ( $\text{NaKCO}_3$ ) and boric acid; a lower flux/sample ratio is used for aluminous materials, and a larger flux/sample ratio is used for zircons. The melt is dissolved and the silica is dehydrated in a mixture of hydrochloric and sulfuric acids with the assistance of polyethylene oxide. The main silica is then determined gravimetrically. Other constituents, including residual silica, are determined on the filtrate combined with the residue remaining after the gravimetric silica determination.

- *Residual silica.* Colorimetric with ammonium molybdate reduced with tin(II) chloride (800 nm) or a mixture of tartaric and ascorbic acids to give the blue reduced heteropolymolybdate (650 nm).
- *Total silica.* Add the gravimetric and residual silica figures.
- *Iron oxide.* Colorimetrically with 1,10-phenanthroline (510 nm). At high levels in chrome-bearing samples, iron from the stock solution is eluted from a cation resin exchange column with

hydrofluoric acid; the iron is then complexed with CyDTA (*trans*-1,2-cyclohexanediamine-*N,N,N,N'* tetraacetic acid) and back-titrated with Zn using xylenol orange indicator. For chrome-bearing samples, a cleanup through an ion-exchange resin is required.

- *Titania.* Colorimetrically with hydrogen peroxide in phosphoric acid (398 nm) or di-antipyrimethane (DAM) at 390 nm. If  $\text{ZrO}_2$  is present, the solution is treated with CyDTA solution first.

- *Lime (calcium oxide).* Titrimetrically with EDTA or EGTA in triethanolamine and potassium hydroxide with a screened calcein indicator. Alternatively with AAS, particularly for  $\text{ZrO}_2$ -containing materials and limestone.

- *Lime plus magnesia.* Titrimetrically with EDTA in triethanolamine and ammonia using methylthymol blue indicator. For chrome-bearing samples, a cleanup through an ion-exchange resin is required first followed by EDTA titrimetry with an Eriochrome Black T indicator.

- *Magnesia (magnesium oxide).* Derived by the difference of the above and lime or directly by AAS, especially if  $\text{ZrO}_2$  is present.

- *Alumina high levels.* Cleaning up into chloroform with cupferron followed by adding excess 1,2-diaminocyclohexanetetraacetic acid (DCTA) or CyDTA and back-titrating with zinc. For chrome-bearing samples, a cleanup through an ion-exchange resin is required.

- *Alumina low levels.* By ICP.

- *Phosphorus (V) oxide.* If  $\text{ZrO}_2$  is present, mask with CyDTA. Then adjust pH and determine colorimetrically with ammonium molybdate reduced in ascorbic acid at 830 nm.

- *Zirconia + hafnia in zircon and zirconia.* Gravimetrically by DL-mandelic acid.

- *Manganese oxide ( $\text{MnO}$ ).* Colorimetrically by oxidation to permanganate with potassium periodate at 524 nm. For chrome-bearing samples, a cleanup through an ion-exchange resin is required.

- *Chromium oxide ( $\text{Cr}_2\text{O}_3$ ).* Up to 0.1% colorimetrically with diphenylcarbazide at 540 nm. Above 0.1% but as a minor constituent, colorimetrically with EDTA at 550 nm. As a major constituent by oxidation to dichromate by peroxodisulfuric acid using a silver nitrate catalyst, destruction of permanganate with HCl and titration against ferrous ammonium sulfate using diphenylamine-4-sulfonate indicator.

## X-Ray Fluorescence Spectrometry

In many ways, modern ceramic analysis is synonymous with XRF, usually combined with the fused,

cast-bead method. This combination is so close to being a universal method that other techniques are regarded as only gap fillers or a cheap alternative. This method of sample preparation and the XRF technique combine ease of preparation, primary calibrations, and better accuracy than can be achieved by 'wet' methods. This has revolutionized ceramic analysis and allowed faster and cheaper analysis for routine samples and, for others (e.g., glazes and colors), has made their analysis economically viable. It also means that very complex materials can finally be analyzed. In 2003, the definitive method ISO12677 was published, which is a standard for the analysis of refractories and refractory raw materials by the XRF fused cast-bead method. The standard features two methods of calibration. One is the synthetic calibration route, used in much of Europe, and the other employs 'Series Reference Materials', an off-the-peg approach used successfully in Japan, which are mixtures of oxides and compounds for short-range calibrations that are checked chemically. Although designed for refractories, ISO12677 will be applied to all ceramics as well as geological materials. It includes uncertainty data that are required under ISO17025: 2000, the Test House Quality Standard.

### Sample Preparation

As implied above, the most popular sample preparation for ceramic analysis by XRF is the fused cast-bead technique whereby the ground but heterogeneous sample is converted into a homogeneous glass by fusing in a flux. Because lithia (lithium oxide) cannot be determined by XRF, and boric oxide is difficult to determine, most XRF fluxes have been based on combinations of lithia and boric oxide. Lithium tetraborate is applied to most basic materials such as magnesite or limestone as well as to oxides such as titania and iron oxide categories ((d) and (e) above). Typical sample flux ratios are: 3:1 for trace analysis on limestone; 5:1 for limestone and dolomite; 10:1 for magnesite, magnesite spinel, magnesite-chrome, iron oxide, and manganese oxide; and 12:1 for zirconia, titania, barium carbonate, and barium titanate.

Lithium tetraborate is not ideal for siliceous materials (categories (a), (b), (c), and much of (g) above), because it is too acidic for an acidic siliceous matrix. A near-eutectic mixture of one part by weight of lithium tetraborate to four of lithium metaborate used at a ratio of 5:1 (w/w) with the sample allows easy fusion of high-silica materials. The lower melting point also permits lower fusion temperatures, aiding the retention of volatile components such as sulfur, and reducible metal oxides such as PbO,

provided oxidizing conditions are maintained. The same flux is equally applicable to silica, alumina, clays, glazes, bone, plaster, dish-washing detergents, talc, and zircon. The fusion temperature is usually 1200°C except where volatiles need to be retained, when 1050°C is used. When one-off samples are analyzed, it is often simpler to analyze them by fusing in this flux as two dilutions, one in Al<sub>2</sub>O<sub>3</sub> and the other in SiO<sub>2</sub>.

Chrome-bearing refractories are particularly difficult to fuse, and, although not entirely satisfactory, a flux mixture of 10 parts of lithium metaborate and 12.5 parts of lithium tetraborate to one part of sample is generally used for chrome–magnesite, chrome–magnesia–zirconia and chrome ore samples, but not metallurgical chrome ore, which requires further dilution in MgO.

The reduced materials (category (f)) require special fusion conditions because dissolution produces an exothermic reaction that can destroy the platinum alloy fusion vessels. For example, the flux used for siliceous materials is reconstituted as lithium tetraborate and lithium carbonate. A SiC or other reduced sample is mixed with lithium carbonate and sintered on top of a protective layer of lithium tetraborate that has been fused and spread over the dish. The weight of the reduced sample therefore needs to be adjusted to maintain the flux to a (oxidized) sample ratio at 5:1. If samples lie in category (c), lithium tetraborate is replaced by boric oxide, which together with the lithium carbonate will ultimately give the appropriate lithium tetraborate/sample ratio (ignited basis).

Having selected the appropriate flux, the preparation of a sample is as follows. The ignited sample is mixed with the appropriate weight of ignited (500°C) flux (or a weight of flux corrected for this ignition) in a platinum/5% gold alloy dish. The mix is fused over a burner or in a 1050°C muffle for reducible samples until the sample is dissolved. The next part of the procedure is that used for all samples where the homogeneous melt is then poured (cast) from a 1200°C furnace into a preheated platinum/5% gold alloy mold, and the subsequent bead, in its mold, is annealed over an air-jet. This generates the fused cast bead. Either surface may be presented to the spectrometer for analysis, provided the surface is used consistently throughout.

There are automatic fusion devices for preparing samples for XRF, but most laboratories preparing a mixture of sample types still prefer a manual process. Because of various new features of XRF, the pressed disc technique, of mixing the ground sample with a binder and pressing in a die, is finding more application. Its use is discussed below.

## Analysis by XRF Spectrometry

Analysis is best exemplified by the most usual class of samples (category (a)). The constituents determined include the eight normally determined by wet-chemical analysis. However, XRF is much more selective than 'wet' methods, so that to obtain a reasonably complete analysis, some or all of the following oxides may need to be determined:  $\text{SiO}_2$ ,  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{K}_2\text{O}$ ,  $\text{Na}_2\text{O}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{Cr}_2\text{O}_3$ ,  $\text{Mn}_3\text{O}_4$ ,  $\text{ZrO}_2$ ,  $\text{HfO}_2$ ,  $\text{BaO}$ ,  $\text{SrO}$ ,  $\text{ZnO}$ ,  $\text{PbO}$ , and  $\text{SO}_3$  (retained after fusion). In addition,  $\text{WO}_3$  must always be determined to allow for the correction for the effects of contamination with tungsten carbide on grinding, both in terms of dilution and the loss on ignition figure. For zircon and zirconia, it is also necessary to determine  $\text{U}_3\text{O}_8$ ,  $\text{ThO}_2$ ,  $\text{SnO}_2$ , and  $\text{CuO}$ . Rare earths are often added to a zirconia matrix, so  $\text{La}_2\text{O}_3$ ,  $\text{CeO}_2$ ,  $\text{Nd}_2\text{O}_3$ , and  $\text{Pr}_6\text{O}_{11}$  are often found as major or minor constituents and the others as impurities.  $\text{Y}_2\text{O}_3$  is added as an alternative to  $\text{CaO}$ ,  $\text{MgO}$ , or  $\text{CeO}_2$  as a stabilizer for zirconia.

With the fused cast-bead technique, synthetic calibration is used to generate a primary calibration needed for referee quality work. Calibration derived from a series of binary standards with a silica base. These same binaries, plus others in alumina, allow quantification of line interference of background effects of one element on another. The third part of the calibration is the determination of mass absorption or  $\alpha$  correction effects (eqn [1])

$$I_T = I_M(1 + \alpha_{ij}C_j) \quad [1]$$

where  $I_T$  is the true intensity of the analyte,  $I_M$  is the measured intensity of the analyte,  $\alpha_{ij}$  is the absorption or enhancement effect on the analyte per percentage of interfering oxide  $j$ , and  $C_j$  is the concentration of that oxide  $j$ . For more than one interfering oxide,  $\alpha_{ij}C_j$  is replaced with  $\sum \alpha_{ij}C_j$ .

These corrections are derived from the binary synthetic beads above, together with appropriate tertiary synthetic beads. With the advent of generally available computer software, there is a move towards theoretically derived corrections either from an Excel spreadsheet or supplied through the instrument manufacturer's software. The calibration for each element involves up to  $(n-1)^2$  line interference effects and  $(n-1)^2$  corrections for each element, plus drift correction.

XRF instrument parameters for ceramics differ from those used for some other materials because of the light element determinations. Rhodium, or less frequently scandium, X-ray tubes are used at voltages in the relatively low kilovolt range. Thallium acid phthalate or layered crystals are used for

soda and magnesia and indium antimonide for silica. Another difference is that in ceramic analysis zirconia, strontia, and lead oxide are frequently present at high concentrations, necessitating the use of longer wavelength lines on a Ge crystal, e.g.,  $\text{ZrL}\alpha$  not  $\text{ZrK}\alpha$ ,  $\text{PbM}\alpha$  not  $\text{PbL}\beta_{1,3}$ . Zirconia causes many line overlaps, so a flow counter is used in preference to a sealed Kr counter in many instances. High-order overlaps are reduced using 30 kV on the X-ray tube rather than 60 kV, so Hf will be determined on the  $\text{L}\beta$  line using a flow counter, narrow collimator on at 30 kV. Lithium fluoride (220) crystals are used in preference to the normal lithium fluoride (220) to separate Ba from Ti peaks.

## Other Uses of XRF

Modern instruments are now being sold with excellent semiquantitative software, light element facilities, and the ability to carry out some speciation. The latter will be dealt with in a separate section below.

There are at least two good semiquantitative packages on the market. These can be used with powders, metals, lumps, pressed discs, liquids and slurries (with He atmosphere), and metal samples. These are very useful for identification or fault finding (e.g., identification of metallic impurities in a slip). With additional information like density, dimension, and elements known to be present or not present, accuracy can be greatly improved. Newer versions of software can be used as an alternative approach to calibration rather than type calibration. Powder samples can be pressed into discs with a wax or  $\text{H}_3\text{BO}_3$  powder or put directly onto a Mylar film and analyzed like liquids.

The major instrument manufacturers can now supply crystals and collimators to determine O, F, C, and B. One manufacturer also claims that Be is possible. Samples in this case are usually ground down or micronized to a particle size similar to that used for XRD below. Wax and  $\text{H}_3\text{BO}_3$  are the best binders. If B and C are required, then two discs are required in the two binders unless the sample is self-binding. Glass and glaze can be analyzed directly, provided a reasonably flat surface is available. Light element analysis is currently of semi- to quantitative quality but work is currently in hand to improve this, as there is a large incentive to avoid the lengthy sample preparations, as discussed above, for a few elements.

A further use of XRF is in depth profiling Pb in glazes. The  $\text{M}\alpha$  line measures the surface and the  $\text{L}\beta$  is used to give a bulk Pb content. This shows Pb redeposition on the surface, which leads to high metal release results.

## Techniques Complementary to XRF

Alternative methods are used where XRF fails, i.e., for elements below sodium in the periodic table, for volatile elements and precious metals not amenable to fusion, for liquids, and for some trace analyses. In the case of trace analysis (in ceramics  $<100\text{ }\mu\text{g per g}$ ), XRF meets the requirements for many elements even with a 5:1 flux/sample ratio, particularly for U, Th, Y, La, V, Rb, Cs, Ga, Ge, Ce, Nd, Pr, Sc, and Ni.

The matrices for trace analysis are generally restricted to silica, alumina, aluminosilicates, cobalt aluminate, limestone, zircon, barium titanate, and zirconia. Sample preparation for the techniques below is similar to those for full analysis by wet methods above, but using purer reagents.

### Atomic Absorption Spectrometry

In ceramics, unlike many industries, AAS has not been greatly used, partly because of chemical and other matrix problems, and partly because XRF appeared on the scene shortly after AAS came into use. Its main application in the ceramic industry has been in the determination of metal release from ceramic ware. This is a class of tests designed to establish the likelihood of lead or cadmium leaching from ceramic ware and involves a 24 h extraction at  $22^{\circ}\text{C}$  with 4% (v/v) acetic acid and subsequent determination of lead and cadmium by flame AAS. Current legislation in the USA is driving limits to a level where atom trap AAS, ICP, or graphite furnace AAS is needed.

Within the greater ceramic community, there is a demand for the use of AAS as part of a wet-chemical analysis. As this is not of interest in Europe, standards are being developed at ISO rather than CEN. Currently, there are methods within ISOTC33 for silica/aluminosilicate/aluminous materials, magnesite and dolomite (ISO10058 revision), zircon/zirconia, and chrome-bearing samples.

For trace analysis, the main ceramic elements of interest are Zn, Pb, Cu, Bi, Sb, Sn, Ag, As, Mn, Cr, Se, and Hg. Many of these are environmentally important. In certain cases the detection limits of flame AAS are inadequate, so that hydride generation for antimony, selenium, arsenic and bismuth, cold vapor for mercury, and graphite furnace AAS for lead and cadmium are required. A variation of AAS is atomic fluorescence, and this is used to achieve the detection limits needed for Hg and Se in environmental samples. Microwave digestion techniques for sample preparation are becoming more common, where, unlike fusion, there is no risk of loss of volatile elements from unfired samples and fewer reagents are

required. This technique scores for batches of samples of similar type.

### Inductively Coupled Plasma Atomic Emission Spectrometry

Inductively coupled plasma atomic emission spectrometry (ICP-AES) is the next most important ceramic instrumental method, and is competitive with XRF at minor determination levels and better at trace levels. Its main use in conventional analysis is in the determination of lithium and boron in glass, glazes, borates, petalite, and magnesite. Sample preparation is identical to that for AAS. Another major use is for the analysis of liquid samples such as acid- or water-soluble salts from clay or bricks, slip liquors, and ceramic waste-product leachates (for landfill, packaging waste, and special waste regulations). A major application of ICP is in the analysis of composition of mortars (BS4551) and concrete (BS1881). Once the separations are complete, ICP gives a very fast series of determinations and greater element coverage. The former means that mortars can be checked during construction and the latter allows a better elucidation of historic mortars. As discussed under AAS, at ISOTC33, ICP is cited as a method of determination of minor constituents as part of a full analysis.

ICP-AES is normally preferred for trace analysis because of its generally better detection limits, freedom from chemical matrix effects, and multi-element capability. When available, it is used instead of AAS. Like AAS, hydride and mercury vapor attachments can be used to enhance the detection limits of the elements listed above. As an alternative to normal sample preparation or microwave procedures, laser ablation is creeping in as an alternative approach. The same pressed discs used for XRF are ablated by an IR or UV laser in a chamber that replaces the spray chamber used normally. The sample preparation takes minutes rather than days or hours, eliminates reagents (even pure reagents are less pure than ceramic powders), and is less susceptible to external contamination.

### Ion Chromatography

Ion chromatography (IC) is capable of determinations impossible by XRF and ICP and can carry out speciation. It is applied mainly to the determination of anions such as  $\text{Cl}^-$ ,  $\text{F}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{SO}_3^{2-}$ ,  $\text{NO}_3^-$  and  $\text{NO}_2^-$ . The determinations are made after sodium carbonate fusion or on water- or acid-soluble extracts. Fluorine is usually separated by pyrohydrolysis, where IC is used as a more sensitive and selective method of determination than the use of ion-selective electrodes. These days it is used for environmental

purposes under IPPC together with additional columns for ammonia, cyanide, and sulfide.

### Single-Element Methods

Even the four techniques discussed above are inadequate for completing all ceramic analyses, and additional methods are required for specific elements:

- *Boric oxide.* A cheaper alternative to ICP–AES is a photometric determination by carminic acid.
- *Carbonate* ( $\text{CO}_3^{2-}$ ). By reaction with acid followed by absorption and weighing of the evolved carbon dioxide.
- *Total carbon, oxygen, and nitrogen.* Usually pyrometrically by commercially available apparatus originally developed for the steel industry.
- *Total sulfur.* Commercially available apparatus employing pyrolysis.

### Speciation

Speciation analysis is particularly demanded for SiC- and nitrogen-containing ceramics, and because species like  $\text{Al}_4\text{C}_3$ , BN,  $\text{B}_4\text{C}_3$ , free aluminum, and free magnesium are being added to ceramics. Another driver is environmental legislation. X-ray diffraction (below) is particularly useful for crystalline species where standards are available. DTA/TGA used in air and an inert atmosphere can be used for the determination of free and SiC carbon in complex silicon carbide materials, especially those containing reactive graphite. XRF can also be used in some instances. Normally the analyst carefully chooses the  $K\alpha$  line for lighter elements or the  $L\alpha$  line for elements for the determination of elements of atomic number 38 (Sr) or above. This is because these transitions are not affected by electronic environment. If the  $L\beta$  line is used for the lighter elements or an L line for the heavier elements, the lines show the effects of chemical environment. These can be manifest in one, two, or three ways – peak shift, a satellite peak, or a shoulder on the peak. A workable method has been developed for  $\text{CrVI}/\text{Cr}^{3+}$  in refractories. Free silica has a peak shift away from both Si and SiC. The generation of a gas into a nitrometer is another useful tool. Some methods being used at present are the following:

- *Free carbon in SiC, etc.* By extended temperature-controlled loss on ignition, using a special apparatus specified by DIN 51075 part 2 (1984) or using DTA/TGA.
- *Silicon carbide.* The elegant way is by the subtraction of free carbon from total carbon and

multiplying by 3.3389. A cheaper alternative is to multiply the analytical total from XRF, including loss on ignition by 2.0060.

- *Free silica.* There are two simple ways, depending on the constituents present. The first is to determine total silica and subtract the Si in free silicon, SiC,  $\text{Si}_3\text{N}_4$  and multiply by 2.1392 or a similar approach using total oxygen, subtracting the O in other species and multiplying by 1.8778. The more elegant method applicable to nitride-bonded silicon carbides is by distillation of  $\text{SiF}_4$  from the sample with HF followed by ICP determination of Si in the distillate and multiplying by 2.1392. The use of the XRF  $K\beta$  line may have potential in this determination.
- *$\alpha$ - $\text{Si}_3\text{N}_4$ ,  $\beta$ - $\text{Si}_3\text{N}_4$ , and  $\text{Si}_2\text{ON}_2$ .* Determine the individual species by XRD and normalize them to the total nitrogen.
- *Sialon* ( $\text{Si}_{(6-z)}\text{Al}_z\text{O}_z\text{N}_{(8-z)}$ ). This determination is similar to the one above and relies on sialon giving an XRD intensity similar to  $\text{Si}_3\text{N}_4$  and calculation from the total nitrogen figure less than that in other nitrogen species. The  $z$  value and hence the formula is calculated by resolving the crystal spacing.
- *Free silicon.* By displacement of silver from silver fluoride or hydrogen into a nitrometer from sodium hydroxide after first washing out free iron and aluminum with acid. If FeSi or FeSi<sub>2</sub> are present, then these need to be determined by XRD and corrections made. XRD also produces accurate silicon results.
- *Free aluminum.* If free silicon and ferrosilicon is low, it can be determined by the free silicon method with a suitable factor. Alternatively, it can be determined by the volume of gas evolved with (1 + 1) HCl and corrected for the free iron content.
- *Free iron.* By bromine/methanol or copper sulfate extraction, followed by ICP determination of Fe.
- *Ferrous iron.* By hydrofluoric acid attack excluding air followed by redox titration with dichromate.
- *Hexavalent chromium.* The method BS1902-9.3, in which the ground sample is extracted with a solution of 2% NaOH/3%  $\text{Na}_2\text{CO}_3$  and the extract is measured spectrophotometrically using diphenyl carbazide at 540 nm.
- *Other inorganic species.* Methods are currently being developed at CEN TC187 WG4.
- *Organic constituents.* Organic constituents are being increasingly used in a ceramic context and their determination may be required in solid samples, organic liquids, gaseous emissions, or aqueous effluents; determination is by gas chromatography (GC) or better by gas chromatography–mass spectrometry (GC–MS) after thermal desorption, solvent extraction, or purge and trap. FTIR and HPLC and colorimetric methods are used for other species.

## Microstructural Analysis

In addition to chemical data on ceramic materials, information on the mineralogical constituents by speciation can be vital to a complete understanding of the material (see above). Both X-ray diffraction (XRD) and microscopic examination can provide such mineralogical information. Additional structural knowledge must be obtained using microscopic techniques.

### X-Ray Diffraction

XRD analysis provides a means by which different crystalline phases are characterized and identified. Samples are normally prepared as finely ground material and then presented to the X-ray beam in such a way that individual crystallites are randomly orientated. Comparison of diffraction traces with standard reference profiles enables the identification of phases to be made. Reference patterns are published by the International Centre for Diffraction Data. In some cases with a careful use of reference materials, internal standards and mass absorption corrections, some quantitative results are obtainable using a variety of mathematical formulas on the peak heights or areas.

XRD may be applied to a wide variety of ceramic problems such as simple phase identifications, crystallite size measurements, and determination of crystal lattice parameters. The mineral assemblages produced during firing or in different service environments can be readily studied. Techniques are now available for micro XRD, in which an intense X-ray beam is collimated or focused onto a specific feature in the sample in order to characterize the crystal structure.

### Microscopy

Microscopic examination can be used in combination with both chemical and XRD results so that interrelationships between phases, grain shapes, and sizes can be examined to give a more complete evaluation. Ceramic materials are generally examined using reflective light microscopy on highly polished sections. Selective etching techniques are employed to enhance features such as grain boundaries and contrasts between mineral phases.

Optical microscopy can be applied to examine porosity, grain size, grain intergrowths, degree and type of ceramic bonding, fracture systems, and identification of contaminants and causes of failure. It can also be used as a tool to predict the likely behavior of materials in a variety of service environments.

Scanning electron microscopy (SEM) can be used in a similar manner, although examination at much

**Figure 1** Spatial distribution of components in a ceramic material (brown fused alumina) as shown by overlaid elemental distribution using energy dispersive analysis.

higher magnification is possible. SEM examination is not constrained to polished flat surfaces and can be applied to rough surfaces such as fractures and powders. Microprobe analysis is often conducted in conjunction with SEM examination and provides quantitative chemical data from areas of samples as small as a few micrometers in size. The high spatial resolution enables analyses to be made on specific crystals, phases, and positions within diffusion profiles. By integrating the control of the electron microscope with a microanalysis system, it is possible to collect spatial chemical information or chemical maps of a sample. These can be false colored to visually differentiate component parts of the sample (Figure 1). Another feature that can be used for electron microscopy is integrating electron diffraction with the microscope so that information on crystal orientation can be obtained. Combining electron diffraction with control of the microscope, grain boundaries can be delineated as points of change of crystallographic orientation.

## CEREBROSPINAL FLUID

**E J Thompson**, The Institute of Neurology, London, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Cerebrospinal fluid (CSF) contains a myriad of analytes. Rather than attempting to give a complete list of all the constituents, the emphasis in this article will be on giving some of the guiding principles for interpretation of the results of analysis. There will also be a critical approach to the methods of collection of CSF, since this can also have a profound effect on the final results of analysis. The interpretation of results also depends primarily on the nature of the analyte.

### What is CSF?

CSF is not a homogeneous fluid, but is derived from various sources. It is therefore relevant to consider, if only in a brief fashion, the source of the various brain fluids, each of which will contribute relatively different amounts of analytes. Studies on the origin of CSF are conveniently described under the four classical headings of anatomy, physiology, biochemistry, and pathology.

#### Anatomy

About two-thirds of CSF is derived from the choroid plexi (blood–CSF barrier) located in the lateral ventricles and eventually finds its way back into the venous blood through the superior sagittal sinus. The other one-third of the fluid is derived from the brain parenchyma, in part from filtration across the blood–brain barrier (see **Figure 1**) and in part from

**Figure 1** Two normal brain barriers that proteins transgress to reach the CSF.

endogenous synthesis within the brain, where water is also produced as an end product of metabolism. As well as flowing over the brain, CSF also goes down the spinal sac to envelop the spinal cord. The most common position in which the needle is inserted for a lumbar puncture to obtain a sample of CSF is at the bottom of the spinal cul-de-sac. However, one can also perform a cisternal puncture through the foramen magnum, as well as a ventricular puncture through a burr hole. The concentration of total proteins is 300% higher in lumbar CSF than in the ventricular fluid. A characteristic protein of ventricular fluid is transthyretin (prealbumin), which is synthesized locally by the choroid plexi. In many species there is significant drainage of the CSF along the cranial nerves, with egress into the lymph nodes of the head and neck. However, this route is of only minor significance in humans. The fluid is propelled by the cardiac pulsations and in humans the total volume is ~150 ml. With a production rate of some

### Introduction

Cerebrospinal fluid (CSF) contains a myriad of analytes. Rather than attempting to give a complete list of all the constituents, the emphasis in this article will be on giving some of the guiding principles for interpretation of the results of analysis. There will also be a critical approach to the methods of collection of CSF, since this can also have a profound effect on the final results of analysis. The interpretation of results also depends primarily on the nature of the analyte.

### What is CSF?

CSF is not a homogeneous fluid, but is derived from various sources. It is therefore relevant to consider, if only in a brief fashion, the source of the various brain fluids, each of which will contribute relatively different amounts of analytes. Studies on the origin of CSF are conveniently described under the four classical headings of anatomy, physiology, biochemistry, and pathology.

#### Anatomy

About two-thirds of CSF is derived from the choroid plexi (blood–CSF barrier) located in the lateral ventricles and eventually finds its way back into the venous blood through the superior sagittal sinus. The other one-third of the fluid is derived from the brain parenchyma, in part from filtration across the blood–brain barrier (see **Figure 1**) and in part from

**Figure 1** Two normal brain barriers that proteins transgress to reach the CSF.

endogenous synthesis within the brain, where water is also produced as an end product of metabolism. As well as flowing over the brain, CSF also goes down the spinal sac to envelop the spinal cord. The most common position in which the needle is inserted for a lumbar puncture to obtain a sample of CSF is at the bottom of the spinal cul-de-sac. However, one can also perform a cisternal puncture through the foramen magnum, as well as a ventricular puncture through a burr hole. The concentration of total proteins is 300% higher in lumbar CSF than in the ventricular fluid. A characteristic protein of ventricular fluid is transthyretin (prealbumin), which is synthesized locally by the choroid plexi. In many species there is significant drainage of the CSF along the cranial nerves, with egress into the lymph nodes of the head and neck. However, this route is of only minor significance in humans. The fluid is propelled by the cardiac pulsations and in humans the total volume is ~150 ml. With a production rate of some

500 ml day<sup>-1</sup>, this means that the fluid is renewed about once every 6 h. The flow rate is slower around the spinal cord because this is in the cul-de-sac.

Turning to the cellular anatomy of the CSF, the normal cell count is up to 4 µl<sup>-1</sup>. This is constituted of approximately two-thirds lymphocytes and one-third macrophages. This comprises an ideal mixture for the production of antibodies. Since the brain has very few lymphatic ducts, it has been argued that one of the main functions of CSF is to act as a kind of lymph for the brain tissue. Under pathological conditions this function becomes especially prominent.

### Physiology

Part of the fluid is derived from the blood as an ultrafiltrate of plasma and part is derived from the brain due to local synthesis of water by glucose metabolism. The brain parenchyma contributes not just water but many analytes. Separate and apart from this, the cells that normally migrate within the CSF also produce analytes. In the blood the main cells are the polymorphonuclear leucocytes, which are, however, rarely found in normal CSF. They may be present in CSF as a result of a traumatic puncture that causes the abnormal contamination of CSF with blood, or as a consequence of various pathological conditions.

Analytes that are derived from the blood plasma can be conveniently divided into those that are actively transported and typically maintained at homeostatic levels, as opposed to those that diffuse down concentration gradients. In between is carrier-mediated transport, which is rate limited typically by a saturable enzymatic transporter system. The passive diffusion of macromolecules such as proteins is influenced by the molecular sieving effect of various barriers that are constituted by basement membranes with varying degrees of effective 'pore size'.

Depending upon where the fluid is sampled along the rostro-caudal neuraxis (ventricular, cisternal, or spinal puncture), there may easily be differences in concentration for particular analytes; for instance, various neurotransmitters synthesized within the thalamic nuclei will have a much higher concentration in the cistern than that found in the spinal cul-de-sac.

### Biochemistry

Perhaps the most important molecular characteristic is that of hydrated size or relative molecular mass ( $M_r$ ), whereas the role of net charge is much less important. The other important characteristic of molecules, especially those of small molecular size, is their degree of lipophilia. For molecules of  $M_r$  less than ~500, the oil-water partition coefficient is the

**Figure 2** Correlation between higher percentage brain uptake (ordinate axis) and increasing lipid solubility (the octanol-water coefficient, modified by the dissociation constant) consequent upon increasing chain length from formate to octanoate (abscissa).

main determinant for entry into the CSF from the serum (Figure 2). In an attempt to bridge the gap between low  $M_r$  and high  $M_r$ , it can be seen that the slopes are not derived from an obvious continuous line of unchanging slope (Figure 3).

Proteins can be conveniently classified according to a kind of quantum rule, in which increasing orders of magnitude for percentage transfer (Table 1) seem to conveniently divide proteins from the two extremes of those synthesized within the brain versus those filtered from the plasma, whilst in between, some proteins are synthesized by the brain to the same extent as other tissues (as opposed to being a 'unique' synthesizer). The remaining proteins seem to be synthesized by the cells that normally inhabit the CSF, the only exception being prealbumin, which shows partial intrathecal synthesis. A more complete list of proteins is given in Table 2.

### Pathology

The presence of significant numbers of polymorphs within the CSF can be iatrogenic, due to traumatic

**Figure 3** Serum/CSF ratio plotted against Stokes hydrated molecular radius,  $R$ . Comparison of low  $M_r$  (left) vs. high  $M_r$  (right) analytes in five stages (I–V) of increasing barrier breakdown. The most dramatic change of slope is in stage V of the low  $M_r$  analytes. The dotted lines also show that it is not a continuous linear function between the two analytes (low vs. high  $M_r$ ). (Reproduced from Felgenhauer K, Liappis N, and Nekic M (1982) Low molecular solutes and the blood cerebrospinal fluid barrier. *Klinische Wochenschrift* 60: 1385–1392; © Springer-Verlag.)

puncture, but is also found in inflammatory disease of the brain. They can synthesize characteristic proteins, such as lactoferrin, lysozyme, and eosinophil cationic protein. There are two other barriers that normally contribute only a minor amount of fluid to the normal CSF, but under various pathological conditions, they can become major contributors. These are the dorsal root ganglia, which can leak large amounts of protein as in Guillain-Barré polyneuropathy. The other source is the meninges, which in various infections, or with carcinomatous deposits, can also give rise to massive increases in the level of CSF proteins.

## Why Analyze It?

The two main reasons why people have traditionally analyzed CSF are: (1) because it represents a kind of

**Table 1** Proteins grouped in order of 'percentage transfer' (or concentration in CSF divided by concentration in serum)

liquid biopsy of the brain and is, by definition, the 'milieu interieur'; and (2) because it is a kind of brain lymph.

Brain proteins are easily recognized since they typically have at least a fivefold higher concentration in CSF than in serum, or the percentage transfer given in **Table 1** is greater than 500%. Although several laboratories have sought marker proteins that might be specific for individual diseases, this has so far not proved a simple solution with 'one protein—one disease'. What is clear, however, is that many brain proteins can be used as indicators of prognosis in response to acute insults such as stroke or physical trauma. Basically, the higher the level of the brain protein in CSF coupled with the longer it persists at high levels, the worse the prognosis.

By far the most common analyses have been conducted through the use of CSF as lymph fluid. Historically, there has been a great deal of work on antibodies in CSF. With continuing improvements in technology, there has been increasing emphasis placed on the analysis of specific antigens. This formation of antibodies can take some 7–10 days. Analysis for antigens is therefore particularly helpful in making the initial diagnosis. In addition, they can also be monitored sequentially to ascertain the effectiveness of therapy for the antigen in question.

**Table 2** The roster of the CSF proteins

Protein	mg l <sup>-1</sup>	% Transfer	% Total
1 Albumin	200	0.5	67

## Sampling – Conditions for the Collection of CSF

Because CSF is not a homogeneous mixture, being derived from multiple sources, it is particularly important to keep precise track of the volume of CSF that is removed. Given the various gradients in concentration of some analytes, which are known to exist along the neuraxis, one should compare the same 'locus' in specimens from different individuals. In humans, for instance, the first 20 ml of spinal fluid comes from the spinal cord, whereas, say, the 15th

milliliter is derived from near the fourth ventricle. In other words, the latter would be CSF similar in composition to that obtained from a cisternal puncture.

When blood is collected, various anticoagulants can be used, not only to prevent clot formation, but also to stop the cascade of various proteolytic enzymes such as the complement series. If these analytes are to be measured in CSF, then it should also be collected in the presence of anticoagulant.

Cells will normally sediment rapidly from CSF to the bottom of the tube, unlike blood plasma that is much more viscous. Nevertheless, it is important to remember that CSF should be centrifuged if the cells may contain the analyte rather than just the supernatant CSF above the cell pellet. Fragments of brain are found in normal spinal fluid and these should be removed by centrifugation. It may thus be of interest to analyze the contents of the pellet as well as that which remains in solution in CSF. It is particularly important to remove cells from CSF before freezing, since lysis of the cells will result. Another source of difficulty with proteins is the use of techniques that involve concentration of CSF prior to analysis, since the proteins will commonly become denatured; also they may not go back into solution when reconstituted following freeze-drying. Due to the very low protein content of CSF, it may be necessary to add inhibitors of proteolysis. This is necessary, for instance, in the case of cytokines, which are not normally destroyed in the blood plasma due to the high concentrations of protein that provide a kind of buffer against hydrolysis by enzymes. In CSF, by contrast, it is essential to use a protease inhibitor such as aprotinin.

The age of the animal can also have a dramatic effect. The CSF total protein is very high in humans in the first few months of life but then decreases. At about age 60 it begins to increase again. Mobility is important, as the circulation of CSF is aided by movement and thus prolonged immobility, for instance, due to coma, can lead to high levels of total protein in the spinal sac. It is therefore important to keep note of any drugs that can reduce the mobility of the patient, likewise any diseases, including psychological effects such as catatonic schizophrenia, which also give rise to less movement and can thus elevate the spinal total protein level. The concentrations of other analytes that depend upon CSF circulation can also be altered.

## Methods of Analysis

The amounts of protein present (see Table 2) can vary over several orders of magnitude. Thus various

**Table 3** Methods of protein detection in order of increasing sensitivity

<i>Sensitivity of solid-phase assays</i>	
Stain:	
Naphthalene black	3 µg per band
Coomassie	1 µg per band
Nigrosine	10 ng per band
Silver	10 ng per band
Enzymatic (HRP)	1 ng per band

Radial (Mancini)	10 mg l <sup>-1</sup>
Electro (Laurell)	5 mg l <sup>-1</sup>
Nephelometry	1 mg l <sup>-1</sup>
Particle counting	1 µg l <sup>-1</sup>
Enzymatic (ELISA)	1 µg l <sup>-1</sup>
Chemiluminometry	10 pg l <sup>-1</sup>
Radioimmunoassay	10 pg l <sup>-1</sup>

HRP, horseradish peroxidase; ELISA, enzyme-linked immunosorbant assay.

From Thompson EJ (1988) *The CSF Proteins: A Biochemical Approach*. Amsterdam: Elsevier; © Elsevier.

different methods are relevant, depending upon the concentration of the protein in question. The assay can be performed in solution on a total amount of protein, regardless of its physical state, e.g., native versus fragments versus aggregates, all of which are typically found in the CSF of normal as well as in altered proportions in abnormal CSF. Additional information is thus available by fractionation with attendant separation of the different physical forms either on the basis of molecular size (e.g., sodium dodecyl sulfate polyacrylamide gel electrophoresis, SDS-PAGE), molecular charge (e.g., isoelectric focusing), or both (e.g., non-SDS-PAGE). Depending on the concentration and/or amount of CSF available for analysis, one would choose the appropriate method to visualize/estimate (Table 3). The cells of the CSF, which typically amount to less than 5 µl<sup>-1</sup>, must not be neglected. If an abnormality is suspected, a cytocentrifuge is an important investigation. A Gram stain is also essential if bacterial infection is suspected. If the level of total protein is normal, bacterial infection is unlikely. CSF lactate is the most discriminating test for bacterial meningitis, having supplanted the less satisfactory determination of glucose.

Determination of CSF albumin and IgG are typically done in parallel with the serum levels of albumin and IgG. This can indicate whether the various blood–CSF barriers are intact and/or whether there is local synthesis of antibody within the central nervous system. It is recommended that the results should be plotted in a nonlinear fashion (Figure 4), especially for measurements of IgA and IgM, since they are

**Figure 4** Use of logarithmic plot to distinguish IgG barrier abnormalities (serum leak) from local synthesis.

much larger proteins than IgG and will therefore show disproportionate leakage with greater destruction of the barriers for the CSF. The most discriminating method (which is also the most widely accepted) for detection of local synthesis of antibodies within the central nervous system is the technique of isoelectric focusing, again of CSF in parallel with serum (Figure 5). Although this is a qualitative test, it is more sensitive than quantitative tests for intrathecal synthesis of IgG, regardless of which mathematical formulation one adopts.

## Applications

Perhaps the most important reason for analyzing CSF is as part of the differential diagnosis of brain inflammation. This inflammation can be either acute or chronic. Probably the most common cause of chronic brain inflammation is multiple sclerosis. About 90–95% of patients with multiple sclerosis will have a typical pattern of immunoglobulin bands called ‘oligoclonal’ in their CSF, which are not found in the corresponding serum when analyzed by isoelectric focusing. As there are various treatments for multiple sclerosis, these can be monitored by longitudinal lumbar puncture to ascertain whether the brain lymphocytes have been suppressed in their production of IgG.

In acute inflammatory diseases, such as bacterial meningitis, the prognosis is inversely correlated with the time required to make the diagnosis. Bacterial meningitis is thus an acute medical emergency.

**Figure 5** Representation of the five patterns of CSF IgG following isoelectric focusing. Densitometry scans show relative proportions of different bands in CSF and parallel serum specimens. Different CSF/SER patterns denote local IgG synthesis. CSF, cerebrospinal fluid; SER, serum; POLY, polyclonal; OLI, oligoclonal; MONO, monoclonal. Cathode is on the right.

The physician should hold the fluid up to the daylight to see if it is turbid (Tyndall effect). If so, antibiotic therapy should be immediately considered. The CSF should then be examined within a short time by microscopy to look for the presence of polymorphs. A Gram stain for bacteria should also be done. Apart from bacteria, acute inflammation can also be due to a number of different viruses that can cause meningitis or encephalitis. Herpes simplex is a DNA virus and herpes simplex infection is treatable using Acyclovir, a drug that acts by blocking replication of the virus. The diagnosis of herpes simplex infection can be made using the polymerase chain reaction. Human immunodeficiency virus (HIV) is a neurotropic virus that primarily enters the microglial cells of the brain. Since HIV infection is associated with immunodeficiency, there are a number of intercurrent infections that tend to appear in the brains of these patients and these can be detected by looking for the appropriate antigens within their CSF. Since the HIV is well known to cause immunoparesis,

traditional diagnostic tests based upon antibody titers may be less useful than antigen tests.

There are many more applications that involve the analysis of CSF but, because of limitations of space, only a selected few of the more pressing applications have been presented. There are entire books devoted to the cells, proteins, and individual brain diseases. For the most recent studies and new markers of disease, see the two texts written in 1999 by Felgenhauer and by Thompson.

## Final Interpretation

The first decision to make is whether the analyte in question is actively pumped or whether it diffuses passively. There is always the caveat of any possible rostro-caudal gradients, in which case the volume removed is important and it is always prudent to measure the levels of analyte in blood plasma (or serum). For proteins with passive diffusion one must correct simultaneously for both the serum level and for an independent measure of barrier function. The quotient of CSF analyte/serum analyte divided by CSF albumin/serum albumin can be expressed as an 'index' value, but if there are alterations in any of the barriers there may be a nonlinear relationship that is particularly characteristic of large molecular weight proteins. This relationship is thus best expressed by a nonlinear function. The golden rule must be to compare like with like, and make appropriate corrections for known differences due to inhomogeneous samples.

### Introduction

Chemical warfare agents are a group of toxic chemicals that have been defined in the Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and their Destruction (commonly referred to as the Chemical Weapons Convention or CWC) as 'any chemical which through its chemical effect on life processes can cause death, temporary incapacitation or permanent harm to humans or animals...'. Poisonous or toxic compounds have been utilized in an effort to gain military superiority throughout history but it is only during the past century that chemical warfare agents have been produced and used on a large scale. Tear gas grenades were used in 1914 by the French at the outbreak of the First World War, but it was not until the Germans first used chlorine near Ypres in 1915 that the world entered the modern era of chemical warfare. Other chemical warfare agents such as phosgene and mustard were weaponized during the First World War and were used by both sides throughout the conflict.

The use and development of chemical warfare agents continued following the First World War

despite the signing of the 1925 Geneva Protocol, which bans the first use of chemical weapons. Mustard was used by the Italians against the Abyssinians (Ethiopia) during the 1936–37 war and just prior to the Second World War, the Germans discovered and produced the first nerve agent, tabun. Tabun was weaponized by the Germans but neither side made use of their chemical weapons stocks. More effective nerve agents, such as VX, were developed in the 1950s, mustard was used in the Yemen War (1963–67) and allegations of chemical warfare agent use were reported in South East Asian conflicts. Nerve and mustard agents were used by Iraq in the 1980s war between Iran and Iraq, and were considered a real threat to United Nations armed forces during their action against Iraq (1990–91). More recently, sarin and mustard were collected in 1992 from a site where chemical weapons were thought to have been previously used against the population of a Kurdish village. Most recently, sarin was released by the Aum Shinrikyo cult in the Tokyo underground transit system (1995) resulting in thousands seeking medical attention and 12 deaths.

After considerable effort the CWC was opened to signature in 1993, with the treaty coming into force on April 29, 1997. More than 160 States Parties have ratified the CWC and agreed not to develop, produce, stockpile, transfer, or use chemical weapons and agreed to destroy their own chemical weapons

and production facilities. A strong, compliance monitoring regime involving site inspections was built into the CWC to ensure that the treaty remains verifiable. The Organisation for the Prohibition of Chemical Weapons, or OPCW, based in The Hague, has responsibility for implementation of the treaty. Routine OPCW inspections have or will take place at declared sites, including small-scale production, storage and destruction sites, and challenge inspections will take place at sites suspected of noncompliance. Proliferation of chemical weapons and their use will hopefully decrease over the coming years as the CWC proceeds toward its goal of worldwide chemical weapons destruction.

Concerns over possible terrorist use, continued interest by the defense community and the requirements of a verifiable CWC, have driven the development and application of analytical methods for the detection, characterization, and confirmation of chemical warfare agents. Analytical techniques play an important role in this process as sampling and analysis will be conducted to ensure treaty compliance, to investigate allegations of use, and to verify the use of these weapons for forensic purposes.

## Chemical Warfare Agent Categories

Chemical warfare agents have been classified into nerve, blister, choking, vomiting, blood, tear, and incapacitating agent categories based on their effect on humans. The most significant chemical warfare agents in terms of military capacity and past use are the nerve and blister agents. For these reasons the analysis of these compounds will be emphasized over the other groups. The choking, blood, and vomiting agents are for the most part obsolete chemical agents that were employed during the First World War. The tear agents were used during the Vietnam War but their primary use, because of their inability to produce high casualties, remains in riot control and for the training of military personnel in chemical defense. Incapacitating agents have been included in the CWC as the United States did develop an agent in this category.

The compounds listed in Table 1 represent the most common chemical warfare agents, by category with their Chemical Abstracts registry numbers, and is not intended to be exhaustive. It has been estimated that more than 10 000 compounds are controlled

**Table 1** Common chemical warfare agents

Full name (trivial name(s))	CA no.
<i>Nerve (react irreversibly with cholinesterase which results in acetylcholine accumulation, continual stimulation of the body's nervous system, and eventual death)</i>	
1-Methylethyl methylphosphonofluoridate (sarin, GB)	107-44-8
1,2,2-Trimethylpropyl methylphosphonofluoridate (soman, GD)	96-64-0
Cyclohexyl methylphosphonofluoridate (GF)	329-99-7
Ethyl dimethylphosphoramidocyanidate (tabun, GA)	77-81-6
O-Ethyl S-(2-diisopropylaminoethyl) methylphosphonothiolate (VX)	50782-69-9
<i>Blister (affect the lungs, eyes, and produces skin blistering)</i>	
Bis(2-chloroethyl)sulfide (mustard, H)	505-60-2
Bis(2-chloroethylthio)ethane (sesquimustard, Q)	3563-36-8
Bis(2-chloroethylthioethyl)ether (T)	63918-89-8
Tris(2-chloroethyl)amine (HN-3)	555-77-1
(2-Chloroethenyl)arsonous dichloride (lewisite, L)	541-25-3
<i>Choking (effects respiratory tract and lungs)</i>	
Chlorine	7782-50-5
Carbonic dichloride (phosgene, CG)	75-44-5
<i>Vomiting (causes acute pain, nausea, and vomiting in victims)</i>	
Diphenylarsinous chloride (DA)	712-48-1
10-Chloro-5,10-dihydrophenarsazine (adamsite, DM)	578-94-9
Diphenylarsinous cyanide (DC)	23525-22-6
<i>Blood (prevents transfer of oxygen to the body's tissues)</i>

under the CWC, although in practical terms the actual number of chemical warfare agents, precursors, and degradation products that are contained in the OPCW database is in the hundreds. The structures of some common nerve and blister chemical warfare agents are illustrated in **Figure 1**.

## Sample Handling

Samples contaminated with chemical warfare agents generally fall into one of the following general categories: (1) munitions or munition fragments (e.g., neat liquid or artillery shell casing) or (2) environmental (e.g., soil, water, vegetation, or air samples), man-made materials (e.g., painted surfaces or rubber), and biological media (e.g., blood or urine). The ease of analysis depends on the amount of sample preparation required to obtain a suitable sample or extract for chromatographic analysis. In the simplest case where neat liquids can be obtained the sample typically only requires dilution with a suitable solvent prior to analysis. Aqueous samples may be analyzed directly or following solvent extraction with an organic solvent, while biological fluids typically require extensive sample handling and/or derivatization prior to analysis. Soil and other solid samples generally require, at a minimum, solvent extraction and concentration prior to analysis.

Soil may be collected following chemical warfare agent contamination and is one of the more commonly analyzed media. Extraction of chemical warfare agents from soil samples may be accomplished using a number of solvents (e.g., hexane,

dichloromethane, or water), with dichloromethane being the most commonly employed extraction solvent for chemical warfare agent determinations. A small portion of soil sample (e.g., 2 g) would typically be ultrasonically extracted with dichloromethane (e.g., 4 ml) in screw-capped glass vial or culture tube for ~10 min. The fines may be removed from the dichloromethane extract by centrifugation or filtration prior to concentration (if necessary) and analysis by gas chromatography–mass spectrometry (GC–MS) or another analytical technique. The sample handling procedures developed for contaminated soils can usually be extended to other solid samples with minor modifications to extraction solvent, volume, or vessel.

## Identification Methods

Chemical warfare agents have often been referred to as warfare gases and, in the military, the phrase ‘gas, gas, gas’ has become synonymous with attack by chemical warfare agents. In fact, many chemical warfare agents exist as liquids at ambient temperatures but have varying degrees of volatility and pose a significant vapor hazard as well as a liquid contact hazard. This physical characteristic has made the analysis of chemical warfare agents amenable to the analytical techniques commonly employed for most environmental analyses, namely GC with a variety of detectors including MS. Synthetic or relatively pure samples are typically characterized by nuclear magnetic resonance (NMR) or Fourier transform infrared (FTIR) spectroscopy. Liquid chromatography–mass spectrometry (LC–MS) has been

used with increasing regularity for the detection and confirmation of chemical warfare agents and their nonvolatile degradation products in aqueous samples and extracts. Thin-layer chromatography (TLC) methods have been thoroughly investigated but have been largely superseded by GC and LC.

The OPCW inspectorate, an important end user of analytical techniques for chemical warfare agents, requires the use of two or more spectrometric techniques and the availability of authentic reference standards for the unambiguous identification of these controlled compounds. For this reason, the combined use of GC-FTIR has received increased attention as newer technologies have led to detection limits approaching those routinely reported during GC-MS analysis. For analyses involving low levels of chemical warfare agents in the presence of high levels of interfering chemical background, tandem mass spectrometry (MS/MS) is often employed.

### Chromatography

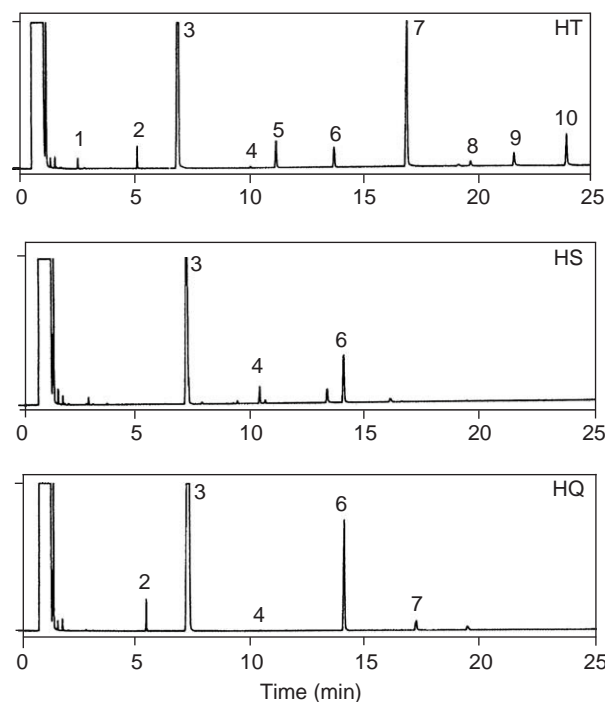

Samples contaminated with chemical warfare agents typically contain multiple components that are best characterized following chromatographic separation. TLC was routinely employed for the detection of chemical warfare agents but with the advent of GC this technology has been used less frequently for analytical applications. Work continues in the area of two-dimensional overpressured TLC with applications being reported for nerve agents. TLC methods have also been proposed for rapid field analyses, but at present this technique sees most application in support of synthetic programs for the isolation of pure materials or as a quick screening procedure.

Capillary column GC remains the most frequently employed analytical separation method for the screening of samples contaminated with chemical warfare agents. Separation of chemical warfare agents may be achieved with many of the commercially available fused silica columns coated with polysiloxane or other films and retention index data relative to *n*-alkanes and alkyl bis(trifluoromethyl)phosphine sulfides (M-series) have been reported for many chemical warfare agents and related compounds. In general, the best separations have been achieved with a moderately polar film such as (86%)-dimethyl-(14%)-cyanopropylphenyl-polysiloxane. Chiral stationary phases have been developed for the resolution of stereoisomers of several chiral nerve agents, most notably soman. The use of multiple columns of differing polarity during one analysis has also been successfully employed during chemical warfare agent analysis and the term

'retention spectrometry' was coined to describe this technique.

Most of the GC detectors commonly applied to pesticide residue analysis have also been applied to the screening of samples for chemical warfare agents with detection limits typically being in the nanogram to picogram range. Flame ionization detection (FID) is routinely used for preliminary analyses as this technique provides a good indication of the complexity of a sample extract. **Figure 2** illustrates typical GC-FID chromatographic separations obtained for three different munitions-grade mustard formulations, HT, HS, and HQ. Mustard comprised 54%, 74%, and 82% of the volatile organic content in HT, HS, and HQ, respectively, based on peak area measurements. The longer chain blister agents, sesquimustard (Q) and bis[(2-chloroethylthio)ethyl]ether (T) were significant in all three samples along with a number of other related compounds that may provide synthetic procedure or source information.

The need for higher specificity and sensitivity has led to the application of element-specific detectors

**Figure 2** Capillary column GC-FID chromatograms of three munitions-grade mustard samples: HT (top), HS (middle), and HQ (bottom). Identified compounds include: (1) 1,4-thioxane, (2) 1,4-dithiane, (3) mustard (H), (4) bis(2-chloroethyl)disulfide, (5) 2-chloroethyl (2-chloroethoxy)ethyl sulfide, (6) sesquimustard (Q), (7) bis(2-chloroethylthioethyl)ether (T), (8) 1,14-dichloro-3,9-dithia-6,12-dioxatetradecane, (9) 1,14-dichloro-3,6,12-trithia-9-oxatetradecane, and (10) 1,16-dichloro-3,9,15-trithia-6,12-dioxaheptadecane. (GC conditions: 15 m  $\times$  0.32 mm ID J&W DB-1; 50°C (2 min) 10°C min<sup>-1</sup> 280°C (5 min).)

such as flame photometric detection, thermionic detection, atomic emission, and electron capture detection. The simultaneous use of FID with one or more element specific detectors has also been demonstrated during dual- or tri-channel GC analysis using conventional and thermal desorption sample introduction. While data obtained with these detectors may provide strong collaborative evidence for the presence of chemical warfare agents, they cannot be used for full confirmation. Use of GC with one or more spectrometric technique such as MS is required to confirm the presence of chemical warfare agents.

LC-ESI-MS is being used increasingly, as electrospray mass spectrometric data may be used to directly identify chemical warfare agents, degradation products, and related compounds in collected aqueous samples or extracts. Both the nerve and blister agents undergo hydrolysis in the environment and methods are required under the CWC for retrospective detection and confirmation of these compounds. These compounds are significant as they would not be routinely detected in environmental samples and their identification strongly suggests the prior presence of chemical warfare agents. The degradation products of the chemical warfare agents, in particular the nerve agents, are nonvolatile hydrolysis products that must be derivatized prior to GC analysis. A variety of derivatization reagents, leading to the formation of pentafluorobenzyl, methyl, *tert*-butyldimethylsilyl, and trimethylsilyl ethers (or esters), have been investigated to allow GC analysis of, in particular, the organophosphorus acids related to the nerve agents (e.g., alkyl methylphosphonic acids and methylphosphonic acid).

### Mass Spectrometry

Mass spectrometry is the method of choice for the detection and characterization of chemical warfare agents, their precursors, degradation products, and related compounds. Extensive use has been made of GC-MS and the mass spectra of numerous chemical warfare agents and related compounds have been published, with the most common chemical warfare agent mass spectra being available in the OPCW, commercial, or defense community databases.

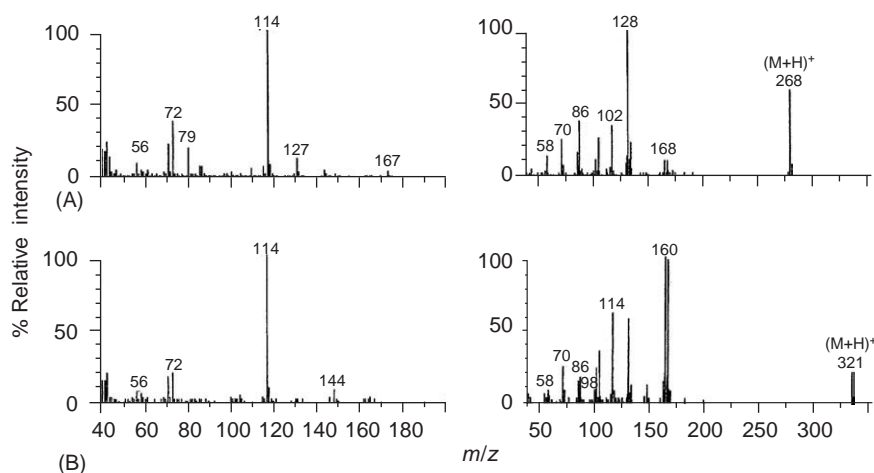

Most of these data were obtained under electron impact (EI) ionization conditions. However, many of the chemical warfare agents, in particular the organophosphorus nerve agents and the longer chain blister agents related to mustard, such as T, do not provide molecular ion information under EI-MS. This hinders confirmation of these chemical warfare agents and makes identification of novel chemical warfare agents or related impurities difficult.

Considerable effort has been devoted to the use of chemical ionization (CI) as a complementary ionization technique. This milder form of ionization generally affords molecular ion information for the chemical warfare agents and has been used extensively for the identification of related compounds or impurities in chemical warfare agent munitions samples and environmental sample extracts. The identity of these related compounds is important because the origin of samples, synthetic process information, or degree of degradation (weathering) information may aid OPCW or other investigations.

Isobutane, ethylene, and methane gases were initially demonstrated as suitable CI gases for the acquisition of organophosphorus nerve agent CI-MS data. The efficacy of ammonia CI-MS for organophosphorus nerve agents and related compounds has been demonstrated and many laboratories now employ this complementary confirmation technique. Ammonia CI not only offers abundant molecular ion data but also affords a high degree of specificity as less basic sample components are not ionized by the ammonium ion. Additional data may be obtained through the use of deuterated ammonia CI, as this technique provides useful hydrogen/deuterium exchange data that indicates the presence of exchangeable hydrogen(s) in CI fragmentation ions. Finally, for full confirmation, the acquired EI and CI mass spectrometric data should be compared to authentic reference data obtained under identical experimental conditions.

Figure 3 illustrates EI and ammonia CI data obtained for VX and a significant VX degradation product, bis[2-(diisopropylamino)ethyl] disulfide. The acquired EI data for both compounds, as well as other VX related compounds, are remarkably similar. Both compounds lack a molecular ion and contain a base ion at  $m/z$  114 due to  $(\text{CH}_2\text{N}(\text{iPr})_2)^+$  and additional ions related to the  $-\text{SC}_2\text{H}_4\text{N}(\text{iPr})_2$  substituent. Under ammonia CI conditions, mass spectra containing pseudomolecular and CI fragmentation ions were acquired, with these data being used to confirm molecular mass and differentiate VX related compounds that exhibit similar EI data.

Capillary column GC-MS/MS offers the analyst the potential for highly specific, sensitive detection of chemical warfare agents as this technique significantly reduces the chemical noise associated with complex biological or environmental sample extracts. The specificity of product scanning with moderate sector resolution, as well as the specificity of ammonia CI, was demonstrated with a hybrid tandem mass spectrometer during analysis of painted panel samples circulated during an international round robin verification exercise.

**Figure 3** EI (left) and ammonia CI (right) mass spectrometric data obtained for (A) VX and (B) bis[2-(diisopropylamino)ethyl] disulfide.

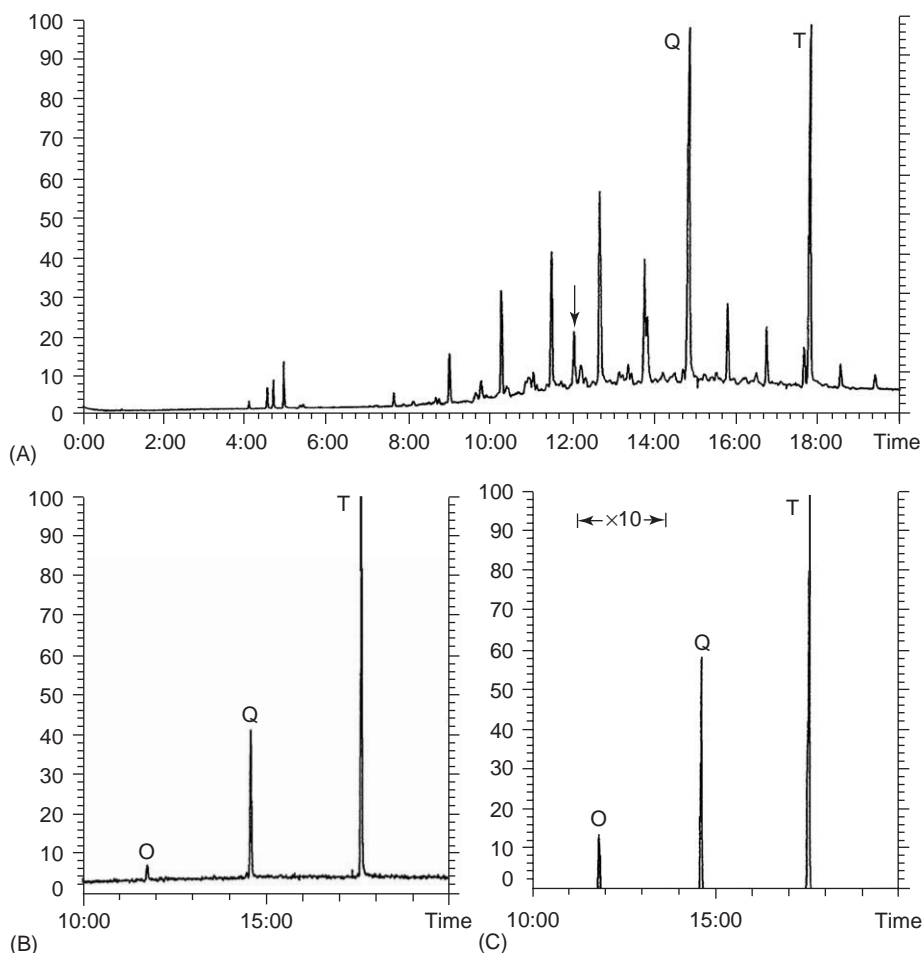

The painted panel extract was contaminated with numerous hydrocarbons and only two of the three longer chain blister agents, sesquimustard (Q) and bis(2-chloroethylthioethyl)ether (T), could be identified during capillary column GC–MS (EI) analysis (Figure 4A). The arrow indicates the chromatographic retention time of the third blister agent, 2-chloroethyl (2-chloroethoxy)ethyl sulfide (O). The specificity of ammonia CI (Figure 4B) was clearly demonstrated during this analysis. All three longer chain blister agents were determined in the presence of high levels of interfering hydrocarbons, as the hydrocarbons were not sufficiently basic to ionize. Similarly, it was possible to use the resolution of hybrid MS/MS to discriminate between ions at  $m/z$  123 arising from the longer chain blister agents from those ions at  $m/z$  123 arising from the hydrocarbon background. The resultant GC–MS/MS chromatogram (Figure 4C), where only  $m/z$  123 ions due to the blister agents were transmitted into the collisional activated dissociation cell, was virtually free of chemical noise and all three components were detected. The three longer chain blister agents were well resolved with the J&W DB-1701 capillary column, with all three components exhibiting similar product spectra during GC–MS/MS analysis.

Both the nerve and blister agents undergo hydrolysis in the environment and methods are required for retrospective detection and confirmation of these hydrolysis products. Hydrolysis products are significant as they are generally compounds that would not be routinely detected in environmental samples and their presence strongly suggests the prior presence of chemical warfare agents. The degradation products of the chemical warfare agents, in particular the nerve agents, are nonvolatile hydrolysis products that

must be derivatized prior to GC analysis. Alternatively, aqueous samples or extracts may be analyzed by LC–MS, negating the need for additional sample handling steps and derivatization.

Use of thermospray MS and more recently the atmospheric pressure ionization (API) (e.g., electrospray (ESI), ionspray, and atmospheric pressure CI) techniques have enabled the direct mass spectrometric analysis of the hydrolysis products of chemical warfare agents. Both techniques may be interfaced to liquid chromatography for component separation, with thermospray having been largely superseded by API for most LC–MS applications. LC–ESI–MS methods have been used for the direct analysis of chemical warfare agent hydrolysis products in a number of studies and have recently been demonstrated for the analysis of nerve agents. These new methods complement existing GC–MS methods for the analysis of chemical warfare agents and their hydrolysis products and LC–ESI–MS methods will replace some GC–MS methods used for the analysis of contaminated aqueous samples or extracts.

Mustard and longer chain blister agents hydrolyze to their corresponding diols, with thiodiglycol being the product formed following hydrolysis of mustard. Figure 5A illustrates a typical LC–ESI–MS chromatogram obtained for the aqueous extract of a soil sample taken from a former mustard storage site. The soil sample extract contained thiodiglycol (Figure 5B) and 6-oxa-3,9-dithia-1,11-undecanediol (Figure 5C), the hydrolysis products of blister agents mustard and bis(2-chloroethylthioethyl)ether, respectively. ESI–MS data for both compounds contained protonated molecular ions that could be used to confirm molecular mass and characteristic lower mass product ions.

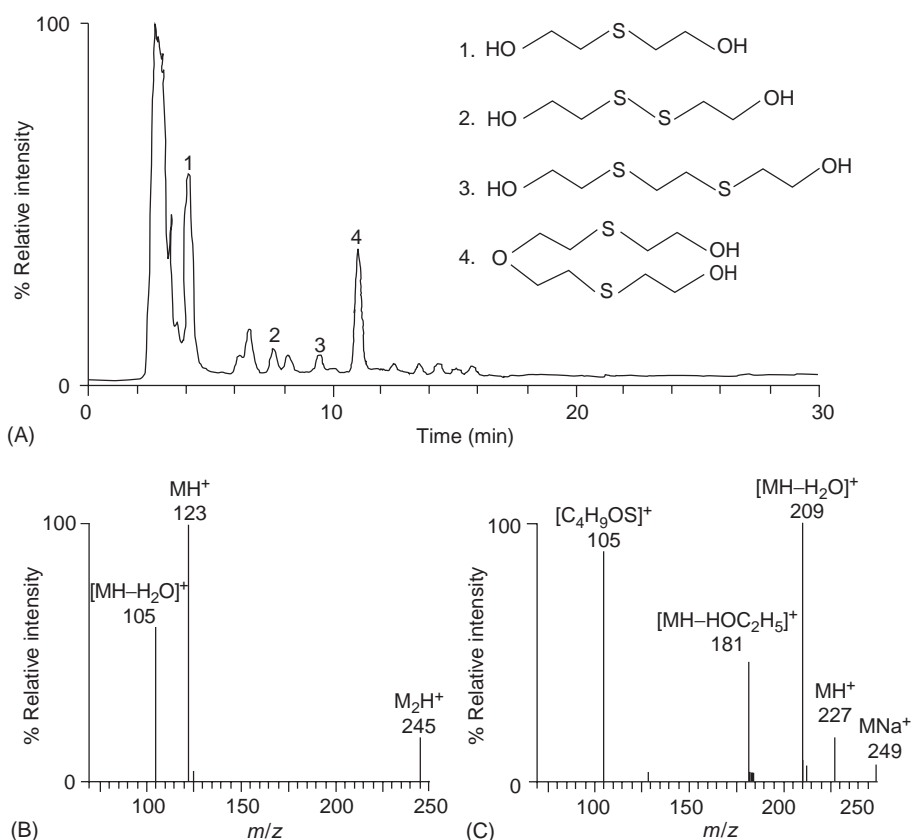

**Figure 4** Capillary column (A) GC–MS (EI); (B) GC–MS (ammonia CI); and (C) GC–MS/MS (EI) chromatograms obtained during analysis of international round robin painted panel extracts. Sequimustard (Q) and bis(2-chloroethylthioethyl)ether (T) were detected during EI analysis. The downward arrow in (A) indicates the retention time of 2-chloroethyl (2-chloroethoxy)ethyl sulfide (O). This compound was masked by the sample matrix during EI analysis and was only detected following (B) ammonia CI and (C) MS/MS analysis. (GC conditions: 15 m  $\times$  0.32 mm ID J&W DB-1701, 40°C (2 min) 10°C min<sup>-1</sup> 280°C (5 min), x-axis: time (min).)

**Figure 6** illustrates the LC–ESI–MS chromatogram for a complex munitions-grade tabun sample. Tabun and a number of related compounds were identified based on their acquired ESI–MS data. The mass spectra contained  $(M + H)^+$ ,  $(M + H + ACN)^+$  ions and/or protonated dimers that could be used to confirm the molecular mass of each compound. Structural information was provided by inducing product ion formation in either the ESI interface or the quadrupole collisional cell of a MS/MS instrument. Product ions due to alkene loss from the alkoxy substituents, and the acetonitrile adduct associated with these product ions, were generally observed. **Figure 7** illustrates typical ESI–MS data obtained for tabun and three other nerve agents.

Considerable effort has been expended on the development of field portable MS and GC–MS

instruments, as this technique holds the greatest promise for the confirmation of chemical warfare agents under field situations. The OPCW has available field portable GC–MS instrumentation that may be taken onsite to confirm the presence of chemical warfare agents. An atmospheric pressure MS/MS has also been developed and evaluated for real-time detection of nerve agents in air. Alternatively, air samples may be collected on solid-phase microextraction fibers or on Tenax tubes that may be thermally desorbed into an onsite GC–MS instrument. Secondary ion mass spectrometry has been used for the detection of chemical warfare agents and their hydrolysis products on leaves, soil, and concrete, offering a new option for the detection of these compounds on adsorptive surfaces. Finally, rapid separation and detection of chemical warfare agents has recently been

**Figure 5** (A) Packed capillary LC-ESI-MS chromatogram obtained for the water extract of a soil sample obtained from a former mustard site. ESI-MS data obtained for (B) thiodiglycol (sampling cone voltage: 20 V) and (C) 6-oxa-3,9-dithia-1,11-undecanediol (sampling cone voltage: 30 V). (LC conditions: 150 mm  $\times$  0.32 mm ID  $C_{18}$ , acetonitrile/water gradient.).

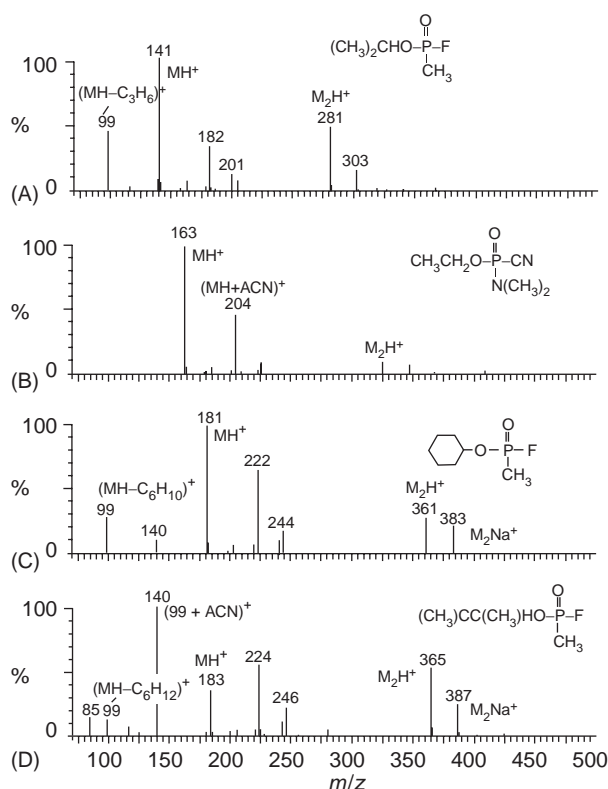

**Figure 6** Packed capillary LC-ESI-MS chromatogram obtained for 0.1 mg  $ml^{-1}$  munitions-grade tabun sample. Tabun (peak number 4) and 15 related organophosphorus compounds were identified by ESI-MS. (LC conditions: 150 mm  $\times$  0.32 mm ID  $C_{18}$ , acetonitrile/water gradient.)

demonstrated with ESI-ion mobility spectrometry (IMS)-MS. IMS is commonly employed in military devices for rapid field detection and this approach could lead to the development of instrumentation for the analysis of aqueous samples.

### Other Techniques

NMR is an important technique for the structural analysis and characterization of chemical warfare agents, particularly for the authentication of reference materials or unknown chemical warfare agents and related compounds. The presence of heteronuclei such as  $^{31}P$  and  $^{19}F$  in the nerve agents leads to diagnostic splitting patterns and coupling constants due to  $^1H$ - $^{31}P$  and  $^1H$ - $^{19}F$  spin-spin coupling. The utility of NMR for analysis of complex sample mixtures or for trace analysis is somewhat limited. Specific heteronuclear experiments such as  $^{31}P$  NMR may be used to identify organophosphorus nerve agents in complex matrices. Characteristic chemical shifts of compounds containing a phosphorus-carbon bond and splittings due to phosphorus-fluorine spin-spin coupling can be used to screen for the presence of nerve agents (Table 2). However,  $^{31}P$  chemical shifts are sensitive to temperature, concentration, and solvent and the identification must be supported with additional spectrometric data such as MS. Two-dimensional correlation experiments have been used to help in structural elucidation of

**Figure 7** ESI-MS data obtained for (A) sarin (GB); (B) tabun (GA); (C) cyclohexyl methylphosphonofluoridate (GF), and (D) soman (GD) with a sampling cone voltage of 20 V.

**Table 2** Phosphorus-31 chemical shifts of nerve agents in deuteriochloroform

Nerve agent	$\delta^{31}\text{P}$ (ppm) <sup>a</sup>	$J_{\text{PF}}$ (Hz) <sup>b</sup>
VX	53.9	—
Soman (two isomers)	29.1	1047
	28.1	1047
GF	28.5	1047
Sarin	28.4	1046
Tabun	−9.8	—

<sup>a</sup>Chemical shift relative to an internal reference standard of triethyl phosphate, −1 ppm.

<sup>b</sup>Spin-spin ( $^{31}\text{P}$ – $^{19}\text{F}$ ) coupling constants.

unknowns in contaminated samples, making NMR a valuable technique to be used alongside other spectrometric techniques.

Condensed phase infrared (IR) data exist for many chemical warfare agents and related compounds as this technique was routinely used prior to the advent of GC–MS. Capillary column GC–FTIR offers considerably more promise for the identification and characterization of chemical warfare agents in multiple component sample extracts and has been utilized as a complementary confirmation technique.

**Figure 8** Vapor phase FTIR spectra obtained for (A) sarin (GB) and (B) mustard (H) during capillary column GC–FTIR analysis.

Sensitivity is generally poorer than that obtained by MS but may be improved by using large volume (e.g., 50  $\mu\text{l}$ ) injections with peak compression onto an uncoated precolumn with lightpipe technology or through the use of cryodeposition.

Figures 8A and 8B illustrates the FTIR vapor phase data obtained for sarin and mustard, respectively. Sarin exhibits characteristic absorption bands at 2991, 1313, 1018, 924, and 843  $\text{cm}^{-1}$  due to C–H, P–F or P=O, P–O–C, P–CH<sub>3</sub>, and P–F, respectively. Mustard contains bands at 2969 and 717  $\text{cm}^{-1}$  that can be assigned to C–H and C–Cl, respectively. The spectra for other chemical warfare agents differ sufficiently such that library searching may be routinely employed for tentative identification.

## Military Detection

A variety of detection devices and other chemical warfare agent defense equipment have been developed for specific military applications. Most of the effort in this area resulted from the perceived threat during the Cold War era and although this threat has decreased dramatically, interest in chemical detection equipment persists because of worldwide chemical weapons proliferation. During the 1990–91 Iraq War chemical detection equipment was deployed into the

Persian Gulf and similar equipment has been used to support the United Nations Special Commission during the destruction of Iraqi chemical weapons. Equipment of this type has been used by the OPCW and could potentially be utilized again by the United

Nations in peacekeeping or intervention roles where the threat of chemical weapons use exists. **Table 3** lists examples of chemical detection equipment by country and indicates the principle of detection and capabilities of each system.

**Table 3** Selected military chemical warfare agent detection devices

<i>Country</i>	<i>Device name and capabilities</i>
Canada	Chemical Agent Detection System (CADS II) – Early warning system that controls a network of Chemical Agent Monitors (see UK) for the real time detection of nerve and blister agents
China	Chemical Warfare Agent Identification Kit, M-75 – Wet chemistry detection of nerve, blister, choking, vomiting, and blood agents
Denmark	INNOVA 1312 Multi-Gas Monitor – Photoacoustic detection of nerve, blister, choking, and blood agents
Finland	Chemical Agent Detection System, M90 – Alarm for the ion mobility spectrometric detection of nerve and blister agents
France	PROENGIN Portable Chemical Contamination Monitor AP2C – Hand-held flame photometric detection of nerve and blister agents – Also designs for fixed sites (AP2C-V and ADLIF)
Germany	MM-1 Mobile Mass Spectrometer – Quadrupole mass spectrometric detection of chemical warfare agents Rapid Alarm and Identification Device – 1 (RAID-1) – Ion mobility spectrometric detection of nerve and blister agents
Hungary	Chemical Agent Sensor GVJ-2 – Ion mobility spectrometric detection of nerve and blister agents Remote Chemical Agent Sensor VTB-1 – Field deployable laser radar for the detection of chemical warfare agents
Romania	Nerve Agent Alarm ASTN-2 – Nerve agent detector based on optical and acoustic signals
Switzerland	IMS 2000 CW Agent Detector – Ion mobility spectrometric detection of nerve and blister agents
CIS (formerly USSR)	Automatic Nerve Agent Detector Alarm, Model GSP-11 – Enzyme inhibition for the detection of nerve agents
UK	Chemical Agent Monitor (CAM), GID-2/GID-3 Detectors – Ion mobility spectrometry based monitor for the detection of nerve and blister agents NAIAD – Nerve agent immobilized enzyme detector and alarm
USA	ICAD Miniature Chemical Agent Detector – Personal detector based on electrochemical principals for the detection of nerve, blister, blood, and choking agents MINICAMS – Gas chromatographic detection of nerve and blister agents M21 Remote Sensing Chemical Agent Alarm (RSCAAL) – Passive infrared detection of chemical warfare agents Chemical Agent Detection Kit, M256A1 – Wet chemistry detection of nerve, blister, choking, and blood agents SAW MINICAD MK II – Surface acoustic wave detection of nerve and blister agents

## Safety and Disposal

Chemical warfare agents are extremely hazardous and lethal compounds. They can only be used in designated laboratories by personnel trained in safe-handling and decontamination procedures and with immediate access to medical support. Safety and standard operating procedures must be developed and approved before any chemical warfare agents are handled. Chemical warfare agents can only be used in laboratory chemical hoods with a minimum face velocity of 100 linear feet per minute equipped with emission control devices that limit exhaust concentration to below  $0.0001 \text{ mg m}^{-3}$ . Personnel handling chemical warfare agents should wear rubber gloves, lab coats, and full faceshields and keep a respirator (gas mask) within easy reach. Sufficient decontaminant to destroy all chemical warfare agents being handled must be on hand before commencing operations.

Blister and nerve agents can be destroyed using saturated methanolic solutions of sodium or potassium hydroxide. Decontaminated chemical warfare agents must be disposed of in an environmentally approved method according to local legislation.

## Introduction

All chemical reactions are accompanied by energy changes, with any excess usually dissipated as heat. However, certain redox reactions yield light (chemiluminescence) at wavelengths from the near-ultraviolet to the near-infrared. Chemiluminescence has been observed in living systems since antiquity and from synthetic compounds since the late nineteenth century. Some commonly observed chemiluminescence emanates from fireflies and the various commercially available 'glow sticks'. These reactions also exhibit analytical utility because the emission intensities are a function of the concentrations of chemical species involved. Routine application of chemiluminescence as an analytical tool did not emerge until the 1970s for gas-phase reactions and the 1980s for liquid-phase reactions. This article will cover the basic principles common to all chemiluminescent reactions and discuss those characteristics that are important for analytical chemistry. The articles that follow in this section will elaborate on the mechanism and analytical applications of specific chemiluminescence reactions. Chemiluminescence in living systems or with reagents originating in living systems is called bioluminescence and is covered elsewhere in this encyclopedia.

## Principles

In a chemiluminescence reaction between species A and B, some fraction of the product species, C, are formed in an electronically excited state, C\*, which

can subsequently relax to the ground state with emission of a photon (reaction [I]):

In some cases, the excited intermediate (C\*) transfers energy to a suitable fluorophore, which may then exhibit its characteristic fluorescence emission (reaction [II]). This phenomenon is referred to as indirect or sensitized chemiluminescence:

Chemiluminescence involves both a luminescence process and a chemical reaction. Consequently, the observed intensity depends upon the rate of the chemical reaction, the number of species excited, and their light emission efficiency (eqn [1]):

$$I_{\text{CL}} = \Phi_{\text{CL}} \frac{dP}{dt} = \Phi_{\text{EX}} \Phi_{\text{EM}} \frac{dP}{dt} \quad [1]$$

where  $I_{\text{CL}}$  is the chemiluminescence emission intensity (photons emitted per second),  $dP/dt$  the rate of the chemical reaction (molecules reacting per second),  $\Phi_{\text{CL}}$  is the chemiluminescence quantum yield (photons emitted per molecule reacted),  $\Phi_{\text{EX}}$  is the excitation quantum yield (excited states produced per molecule reacted), and  $\Phi_{\text{EM}}$  is the emission (luminescence) quantum yield (photons emitted per excited state).

The excitation quantum yield ( $\Phi_{\text{EX}}$ ) is the product of the efficiencies of (1) the chemical reaction, (2) the conversion of chemical potential into electronic excitation energy and in the case of sensitized chemiluminescence, and (3) the energy transfer. As a consequence, most chemiluminescent reactions have relatively low quantum yields compared to those of photoluminescence; the exception being the enzymatically mediated bioluminescent processes. In spite of this low quantum efficiency, chemiluminescence remains an attractive option for chemical analysis. This stems from three factors: (1) improved

signal-to-background and signal-to-noise ratios due to the absence of an excitation source; (2) inexpensive and robust instrumentation; and (3) increased selectivity due to the limited number of available reactions.

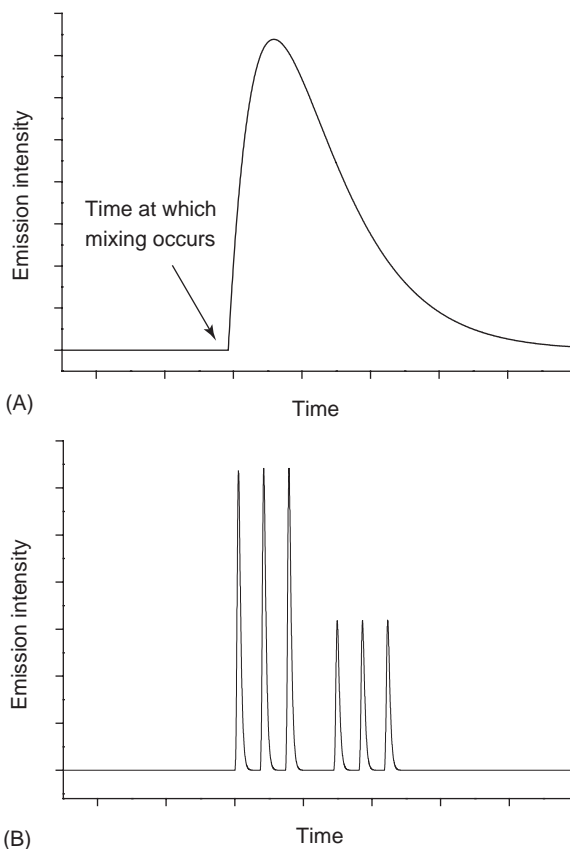

The energy for the creation of the electronically excited state comes from the chemical reaction. For emission in the region from the near-infrared to the near-ultraviolet, a reaction liberating between 130 and  $340 \text{ kJ mol}^{-1}$  is required. This amount of energy usually comes from bond cleavage or electron transfer. In systems involving bond cleavage (e.g., luminol or peroxyoxalates), the reagent can be used only once. However, some electron transfer reactions (including those of the radical ions of rubrene and *p*-benzoquinone or tris(2,2'-bipyridyl)ruthenium(III)) elicit emission without bond cleavage or rearrangement and as such the reagents can be recycled.

## Reaction Kinetics and the Observed Signal

Unlike photoluminescence, where the rate of emission reflects the lifetime of the excited state, the rate of generation of light from a chemical reaction is dependent on reaction kinetics. Consequently, the chemiluminescence emission intensity is inherently transient as illustrated in **Figure 1A**, which shows the variation of intensity with time after mixing the reactants. The overall timescale can vary from a short flash lasting less than a second to a pseudocontinuous glow lasting minutes to hours, depending upon the reaction involved and the concentration of reactants.

There are two basic approaches to employing chemiluminescence for analytical detection: static solutions and flow analysis. With the former, discrete portions of the reagent(s) and analyte are mixed in front of a detector and the chemiluminescence intensity versus time profile is monitored (**Figure 1A**). Generally, the height or area of the peak is measured and correlated with analyte concentration, but the temporal distribution of this signal can also be exploited. Analytes that react at different rates will produce disparate intensity-time profiles. In cases where the chemiluminescence kinetics are reproducibly distinct for two or more compounds, the possibility exists for mathematical deconvolution of signals resulting from mixtures of analytes and hence enhanced selectivity without a separation step.

With respect to flow analysis methodologies (including flow injection, sequential injection, pulsed flow, and chromatography), the analyte and reagent(s) are propelled in streams and merged to initiate the reaction close to or within a detection cell. As a consequence, the observed signal is dependent

**Figure 1** (A) Intensity versus time profile recorded from a static solution in a batch luminometer after a triggering reagent has been added. (B) Two sets of triplicate sample injections using a flow analysis system.

upon the reaction kinetics and the physical parameters of the flow system. These include the volume between the confluence and observation points, the flow cell geometry, and the flow rate. In order to achieve the desired sensitivity, these parameters require optimization. In the case of particularly fast reactions, it is crucial that the mixing occurs as close as practicable to the point of detection. Some typical flow analysis response profiles are shown in **Figure 1B**. If the reagent and analyte are continuously combined a steady-state signal will arise and this, coupled with a spectrofluorimeter, allows the collection of chemiluminescence spectra.

## Chemiluminescence versus Fluorescence Detection

Chemiluminescence and fluorescence have the potential for low detection limits and wide linear calibration ranges. Both are sensitive to environmental conditions (solvent type, the presence of quenchers, pH, ionic strength, and temperature) that may alter the quantum efficiency of emission. In addition, these

factors significantly affect the rate of the chemiluminescence reaction and the chemi-excitation efficiency and as such require control to ensure analytical precision. Fluorescence instrumentation is more complex than that employed for chemiluminescence, as the former requires an excitation source and two monochromators. Consequently, chemiluminescence measurements do not suffer from source fluctuation noise or light scattering. As a result, chemiluminescence detection can sometimes afford superior detection limits compared to those achievable with fluorescence. On the other hand, the spectrofluorimeter provides measurement versatility not possible with chemiluminescence: selection of emission and excitation wavelengths, source intensity and excitation beam size, and location. Many chemiluminescence reactions exhibit a measurable chemical background (or blank) signal, which can degrade detectability. In principle, a fluorescent molecule can be excited more than once in a given measurement, whereas very few chemiluminescence agents can be regenerated (a notable exception is tris(2,2'-bipyridyl)ruthenium(III)). Nevertheless, the use of intense excitation sources in fluorescence to maximize the signal is limited by problems of photodecomposition.

## Selectivity

Unlike photoluminescent techniques, where some degree of selectivity is often derived from the intrinsic excitation and emission wavelengths of the analyte, the inherent selectivity of chemiluminescence detection arises from the limited number of chemical reactions that produce significant amounts of light. Furthermore, wavelength discrimination usually offers no advantage to the chemiluminescence detection, as different analytes often lead to the same emitting species, and should be avoided due to the detrimental effect on sensitivity.

Selectivity of chemiluminescence reactions can be a concern. Some reactions are essentially compound-specific. An example is tetrakis(dimethylamino)ethylene, which undergoes chemiluminescence reaction only with  $O_2$ . Although such specificity provides freedom from measurement interference, that chemiluminescence reaction then lacks universal application. In other cases, several species could yield emission with a given reagent. These situations then require coupling of the chemiluminescence detection with some sort of highly selective physical or chemical step (such as chromatography, immunoassay, enzyme reactions) to achieve an interference-free measurement. An

example of this type of chemiluminescence reaction would be the metal-ion catalyzed oxidation of luminol by transition metals. Many transition-metal ions and organometallics will yield intense chemiluminescence emission upon reaction with an alkaline solution of luminol and hydrogen peroxide. The emission emanates from the oxidation product of luminol, thus there is no spectroscopic way to identify which metal-ion catalyst was responsible for the emission.

## Corrected Emission Spectra

Chemiluminescence spectra provide possible insights into the nature of the emitting species and consequently should be mandatory for any speculation concerning the light-producing pathway. Clearly, this is not the case with indirect chemiluminescence as the emission is identical to the photoluminescence of the added fluorophore. As with photoluminescence, chemiluminescence emission spectra should be corrected for the wavelength dependence of the detector response and monochromator transmission. A correction factor can be created with a lamp of known spectral irradiance or with fluorescence emission standards. Correction is particularly important for broadly distributed bands and those extending into the near-infrared region where the sensitivity of most instruments is poor. For example, the uncorrected emission spectrum from the oxidation of urea with alkaline hypobromite appeared to be broadly distributed across the visible region with a maximum at 510 nm. After correction, the maximum was at  $\sim 710$  nm.

## Gas-Phase Reactions

Numerous gas-phase chemiluminescence reactions have been studied and several of them commercialized for atmospheric monitoring and gas chromatography (GC) detection. **Table 1** and the discussion that follows highlight a few of the most important reactions. More details on gas-phase chemiluminescence is contained in a subsequent chapter. These reactions can be grouped into two categories: those occurring at room temperature and those occurring in flames between high-energy molecular or atomic species.

The most well-known flame chemiluminescence reactions are for sulfur and phosphorus detection. These form the basis of flame photometric detectors used in gas chromatography. When sulfur compounds are pyrolyzed in a hydrogen-rich flame, excited diatomic sulfur is formed as illustrated in

**Table 1** Selected gas-phase chemiluminescence reactions

Analyte	Reagent(s)	Emitter	Wavelengths
Ozone	Ethylene or other alkenes	Numerous	Visible and near-IR
Nitric oxide (NO)	Ozone	NO <sub>2</sub>	Visible and near-IR
Nitrogen compounds	Ozone after conversion to NO	NO <sub>2</sub>	Visible and near-IR
Phosphorus compounds	Hydrogen-rich flame	PHO	526 nm
Sulfur compounds	Hydrogen-rich flame	S <sub>2</sub>	384 nm
Sulfur compounds	H <sub>2</sub> flame followed by ozone	SO <sub>2</sub>	360 nm

reaction [III]:

The emission from S<sub>2</sub> is an intense blue and is monitored through a filter at ~400 nm, thus eliminating interference from the flame. The calibration function has a squared dependence on the analyte concentration, as the chemiluminescence reaction involves two sulfur atoms. This detector is especially good for sulfur dioxide, carbon disulfide, methyl mercaptan, and hydrogen sulfide. Similarly, burning of phosphorus compounds yields emission from PHO\*, which is monitored at 526 nm. The phosphorus flame photometric detector yields linear working curves for over four decades and is useful for detection of phosphorus-containing pesticides.

Analytically useful chemiluminescence can be generated from room-temperature gas-phase reactions with ozone for the determination of olefins, nitric oxide, metal carbonyls, nonmetal hydrides, and other species. The reaction of ozone with ethylene (or other olefins) yields emission in the range from 300 to 600 nm. Using a constant flow of ethylene as the reagent, this reaction can be used for monitoring atmospheric ozone over a four-decade concentration range with a detection limit of three parts in 10<sup>9</sup> by volume air. This reaction is also the basis of a GC detector for hydrocarbons with detection limits in the nanogram range. Elevated reaction temperatures (>200°C) are required to detect either aromatic or saturated hydrocarbons.

The reaction of ozone with nitric oxide (reaction [IV]) has been utilized for several analytical applications, including the determination of atmospheric nitric oxide, which has a linear response over six orders of magnitude and a detection limit of about one part in 10<sup>12</sup> by volume. The wavelength distribution of this chemiluminescence ranges from the visible to the near-infrared:

This reaction can also be applied to a variety of analytes following their conversion to nitric oxide. For example, *N*-nitrosoamines can be detected at

picogram levels after pyrolytic decomposition at temperatures between 300°C and 350°C as utilized in the GC detector erroneously termed a thermal energy analyzer. Additionally, catalytic oxidation with molecular oxygen at 800–1000°C will yield nitric oxide from nitrogen-containing compounds, which can be used instead of the Kjeldahl determination for total nitrogen. Nitric oxide can also be produced by reacting organic compounds with nitrogen dioxide at a heated gold catalyst; thereby extending this type of chemiluminescence detection to a variety of analytes that do not contain nitrogen. Interestingly, saturated and chlorinated hydrocarbons give no response under these conditions, which provides a limited degree of selectivity.

The reaction between ozone and SO (see reaction [V]) elicits chemiluminescence between 260 and 480 nm and is the foundation of an alternative sulfur detector that is commercially available for use with gas, supercritical fluid, and liquid chromatography. The SO is created from sulfur-containing analytes by burning the chromatographic effluent in a hydrogen flame:

The detection limits are ~20 times better than the flame photometric detector and the response is linear with concentration over five orders of magnitude.

## Liquid-Phase Reactions

Liquid-phase chemiluminescence reactions have been extensively studied and applied to flow analysis, high-performance liquid chromatography, capillary electrophoresis, and batch luminometers. Some of the more important chemistries are listed in Table 2. The discussion that follows will highlight three reactions, which have each been selected to illustrate certain unique attributes. Much more detail on liquid-phase chemiluminescence can be found in a subsequent chapter.

Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) is one of the most commonly used liquid-phase chemiluminescence reagents. In aqueous alkaline

**Table 2** Selected liquid-phase chemiluminescence reactions

Reagent(s)	Analytes	Emission max.
Luminol (alkaline)	Transition metal ions, H <sub>2</sub> O <sub>2</sub> , peroxidase, reactive oxygen species	425 nm
Lucigenin (alkaline)	Transition metal ions, reactive oxygen species	440 nm
Tris(2,2'-bipyridyl)ruthenium(III) (acidic)	Amines, amino acids, oxalate, NADH, some alkaloids	610 nm
Potassium permanganate (acidic with polyphosphates)	Catechols, catecholamines, indoles, ascorbic acid	690 nm
Peroxyoxalates (alkaline)	Fluorescent compounds and analytes derivatized with suitable fluorophores	Dependent on fluorophore

solution, luminol is oxidized to yield excited-state 3-aminophthalate, which emits at  $\sim 425$  nm (reaction [VI]):

Various oxidants (including potassium permanganate, sodium hypochlorite, and iodine) can be used but hydrogen peroxide is the most common. The use of hydrogen peroxide requires a catalyst and these include transition metal cations (such as Co(II), Cu(II), and Fe(III)), potassium hexacyanoferrate(III), or certain metallo-complexes (hemin, hemoglobin, peroxidases). Within limits, the chemiluminescence emission intensity is directly proportional to the concentration of luminol, hydrogen peroxide, or catalyst; consequently, this reaction has been used to determine all of these species. Many applications have resulted from the luminol-based determination of hydrogen peroxide that is generated by reactions of oxidase enzymes with appropriate substrates; in this way analytes such as glucose, cholesterol, uric acid, sucrose, and glucoside metabolites can be quantified. Approximately 20 catalysts can also be determined using this chemistry; these include horseradish peroxidase, microperoxidase, Co(II), Cr(III), and Cu(II) at sub-nanomolar levels. Peroxidases are common labels for immunoassays, and as such luminol chemiluminescence is a useful method for their sensitive determination. The structurally related compound iso-luminol finds application as a chemiluminescent label in both immunoassay and for pre-column chromatographic derivatization.

The light generated from the oxidation of substituted diaryloxalate esters with hydrogen peroxide, in the presence of a fluorophore, is known as peroxyoxalate chemiluminescence (see reaction [VII]). This group of reactions is highly sensitive to base

catalysis by potassium hydroxide or benzyltrimethylammonium hydroxide, and exhibit the highest non-biological chemiluminescence quantum yields (up to 30%):

In these systems, a high-energy intermediate excites a suitable fluorophore, which then emits its characteristic fluorescence spectrum; consequently, they are termed indirect or sensitized chemiluminescence. The most common analytical application has been as a postcolumn reaction detector for liquid chromatography. Various fluorescent analytes (polycyclic aromatic hydrocarbons and polycyclic aromatic amines) and compounds derivatized using dansyl chloride, fluorescamine, or *o*-phthalaldehyde have been determined with sub-femtomole detection limits.

In the tris(2,2'-bipyridyl)ruthenium(II) [Ru(bipy)<sub>3</sub><sup>2+</sup>] system, an orange emission centered at 610 nm results from the excited state [Ru(bipy)<sub>3</sub><sup>2+</sup>]\*. Central to the utilization of this type of chemiluminescence is the generation the reactive oxidant tris(2,2'-bipyridyl)ruthenium(III) [Ru(bipy)<sub>3</sub><sup>3+</sup>] and its subsequent reaction with a reductive analyte, as shown in reaction [VIII]:

In the vast majority of applications the reagent has been electrochemically generated, but there are also

examples where simple redox chemistries have been employed with equal efficacy. Notwithstanding the method of reagent production, this chemistry has been employed to sensitively and selectively detect a variety of analytes including sodium oxalate, NADH, amino acids, antibiotics, opiates, and pharmaceuticals.  $\text{Ru}(\text{bipy})_3^{2+}$  can be used as a label for immunoassay or DNA probes. Importantly, as electron transfer rather than bond cleavage or rearrangement leads to the excited state and the reaction results in regeneration of the  $\text{Ru}(\text{bipy})_3^{2+}$ , it is possible to perform analyses with no net consumption of the reagent.

## Solid-Phase Reactions

In contrast to the large number and extensive application of chemiluminescence reactions in the gas and liquid phases, the use of solid-phase chemiluminescence reactions is limited. The oxidation of many organic compounds is accompanied by weak chemiluminescence. Measurement of this emission can be used to characterize oxidative changes in materials (such as polymer degradation due to exposure to heat or ionizing radiation, or flavor alteration in foods) and to evaluate stabilizers that are used to retard these processes. The oxidation of polymers often results in the formation of peroxides, cross-linking, and chain cleavage. Polyolefins, polyamides, rubber, epoxies, lubricating oils, and edible oils are examples of some materials characterized by chemiluminescence. Measurements on solids involve heating at a controlled temperature (25–250°C) in front of the detector and monitoring the intensity of chemiluminescence emission over time. The shape of the chemiluminescence intensity versus time profile is characteristic of particular materials and can help determine their composition or histories. In the presence of oxygen, the chemiluminescence is

proportional to the rate of oxidation. In the absence of oxygen, the emission is due to decomposition of previously formed peroxide groups. Nevertheless, in both cases the mechanism involves formation of excited-state aldehydes or ketones, and the emission intensity can be enhanced by the addition of highly fluorescent molecules (such as substituted anthracenes).

## Introduction

Although many liquid-phase chemiluminescence reactions have been observed and investigated, only a

limited number of reagents are responsible for the majority of analytical applications; these include acidic potassium permanganate, acridinium esters, diaryloxalates, dioxetanes, hypohalites, luminol, and tris(2,2'-bipyridyl)ruthenium(III). The elucidation of reaction mechanisms for chemiluminescent processes is highly desirable to facilitate improvement of the overall quantum efficiency and hence the analytical figures of merit. Knowledge of the mechanism

involved enables structural and environmental changes to be made on a fundamental rather than an empirical basis. The major stumbling block to the understanding of many chemiluminescent reaction mechanisms is the isolation and characterization of the key intermediates of the reaction pathways. In spite of these difficulties, a significant body of work exists on this area and some of the proposed mechanisms for the more analytically useful chemiluminescent systems are summarized in the following sections. This is complemented with a discussion on the application of these detection chemistries with flow analysis, high-performance liquid chromatography (HPLC), capillary electrophoresis, immunoassay, and DNA assays.

### Acidic Potassium Permanganate

The earliest use of acidic potassium permanganate as a reagent for chemiluminescence is most probably attributable to A.A. Grinberg, who in 1920 observed emission of light during the oxidation of pyrogallol. Since that time, this reagent has been employed under a variety of conditions to elude chemiluminescence from a wide range of analytes. The nature of the emitting species in these reactions has been the subject of considerable conjecture over the past three decades; candidates have included fluorescent oxidation products of the analyte, a triplet dimer of carbon dioxide, singlet oxygen, sulfur dioxide, molecular nitrogen, nitric oxide, and manganese(II). However, it was not until 2002 that the necessary spectroscopic and chemical evidence was obtained to confirm several previous postulations that the emitter was an excited manganese(II) species. In common with tris(2,2'-bipyridyl)ruthenium(II) chemiluminescence, the emission from acidic potassium permanganate reactions is an example of solution-phase chemically induced phosphorescence.

With respect to the analytical applications, ~100 papers have been published since the first report by Stauff and Jaeschke appeared in 1975. The applications can be broadly divided into two classes: inorganic (e.g.,

sulfur dioxide, sulfite, hydrogen sulfide, manganese(II), hydrazine, hydrogen peroxide, and iron(II)) and organic (e.g., opiate and strychnine alkaloids, catechols, catecholamines, indoles, ascorbic acid, and a variety of pharmaceuticals). The majority of these analyses were undertaken using flow analysis or HPLC; the efficacy of this detection chemistry has also been demonstrated with capillary electrophoresis. The utilization of this chemiluminescence has not been as extensive as some other systems. Nevertheless, acidic potassium permanganate can sensitively detect molecules containing phenolic and/or amine moieties and therefore it has considerable potential for the determination of a wide range of important analytes.

### Acridinium Esters

Acridinium phenyl esters react with alkaline hydrogen peroxide to yield excited state *N*-methylacridone, which then emits at ~40 nm (**Scheme 1**). Acridinium esters are structurally related to lucigenin (bis-*N*-acridinium nitrate), which is one of the classic organic chemiluminescence reagents. Both luminol and lucigenin react with alkaline hydrogen peroxide and are catalyzed by transition-metal ions, but the chemiluminescence reaction between acridinium esters and hydrogen peroxide does not require catalysis.

Although acridinium esters can be used to determine hydrogen peroxide, they are more commonly used as labels for immunoassay or DNA probes. As no catalyst is required, acridinium ester chemiluminescence has a lower chemical blank than the oxidation of luminol and therefore has superior detection limits. A strongly alkaline solution (pH 12–13) is required, but under these conditions acridinium esters undergo reversible conversion to the non-chemiluminescent pseudobase form (**Scheme 1**), which slowly decomposes. As a consequence, acidic hydrogen peroxide is added to reconvert the pseudobase to the acridinium ester before the chemiluminescence reaction is initiated with a sodium hydroxide solution.

**Scheme 1**

## Diaryl Oxalates and Oxamides

Indirect (sensitized) chemiluminescence was first reported by E.A. Chandross in 1963 as a result of the reaction between oxalyl chloride and hydrogen peroxide in the presence of 9,10-diphenylanthracene (DPA), as shown in reaction [I]. The observed transient blue emission corresponds to the fluorescence of the aromatic hydrocarbon and is generated via energy transfer from an excited-state reaction intermediate:

A few years later it was discovered that certain substituted esters and amides of oxalic acid could also induce chemiluminescence from suitable fluorophores in the presence of hydrogen peroxide. This class of chemiluminescent reactions has become known trivially as ‘peroxyoxalate’.

In stark contrast to most other nonbiological chemiluminescence reactions, the overall quantum yield for certain peroxyoxalate systems under optimum conditions can range from 0.13 to 0.34. Unlike luminol, the properties of reactivity, energy conversion/transfer, and luminescence are not the province of a single molecule, and theoretically a fluorophore with a quantum yield tending toward unity could be coupled with an oxalate or oxamide designed to give the largest possible quantity of the key high-energy reaction intermediate. The best chemiluminescence quantum yields have been obtained with certain bisphenyloxalates and oxamides that have electron-withdrawing substituents. For example, by reacting compound (1) with hydrogen peroxide in dimethylphthalate and employing rubrene as a fluorophore, an overall quantum yield of 0.23 has been achieved. In analogous fashion, compound (2) initiated chemiluminescence from 1-chloro-9,10-bis(phenylethynyl)anthracene with a quantum efficiency of 0.34.

The electron withdrawing power of the trifluoromethylsulfonyl (triflyl) group attached to the nitrogen activates the oxamide toward the reaction with hydrogen peroxide. However, the correlation of the electron withdrawing power of the substituents with efficiency of light production is limited; the 2,4,6-trichloro isomer of compound (2) is less than half as efficient under identical reaction conditions. Peroxyoxalate chemiluminescence is quite versatile with several reagents showing efficacy with an array of fluorophores that have first excited singlet state energies in the range from 200 to 440 kJ mol<sup>-1</sup> (600–270 nm). Generally, analyte molecules with low first excited singlet state energies and high fluorescence quantum yields exhibit the best overall efficiency. However, there are many exceptions to this simple model and a quantitative relationship between chemiluminescent quantum yield and singlet excitation energy does not exist.

The mechanism of peroxyoxalate chemiluminescence centers on the nature of the postulated ‘key intermediate’ and its mode of interaction with, and excitation of, the fluorophore. An early proposal for this key intermediate, the highly strained 1,2-dioxetanedione, was confirmed more than three decades later using low-temperature <sup>13</sup>C nuclear magnetic resonance spectroscopy in combination with *ab initio* calculations. As shown in Scheme 2, the formation of the key intermediate is subject to both nucleophilic and general-base catalysis by concurrent mechanisms.

Spectroscopic analysis of peroxyoxalate chemiluminescence also revealed several other, as yet unknown, transient entities. The next step in the proposed mechanism was the formation of a charged transfer complex (between 1,2-dioxetanedione and the fluorophore) that decomposes to yield the

Scheme 2

fluorophore in the excited state. Evidence obtained from mechanistic studies on the thermally induced chemiluminescent reactions of dioxetanes and dioxetanones led to a modification of this excitation step. After oxidation of the fluorophore, the charge transfer complex undergoes loss of one molecule of carbon dioxide to produce a radical ion pair. The subsequent annihilation of the two radical ions affords the fluorophore in the excited state. This is commonly termed chemically initiated electron exchange luminescence (CIEEL).

A detailed kinetic investigation of the reaction between bis(pentachlorophenyl)oxalate and hydrogen peroxide with sodium salicylate as a catalyst and 9,10-diphenylanthracene as the fluorophore in chlorobenzene solvent supported the CIEEL approach. This study predicted a linear dependence of light intensity on initial hydrogen peroxide concentration together with a direct proportionality between overall quantum yield and the oxidation potential of the fluorophore. Both these predictions have been experimentally verified. Studies employing various oxalate esters in solvent systems containing small amounts of water have revealed an even more complex mechanism. This is manifested by the observation of two maxima in the intensity–time profile of the chemiluminescent reaction. The result has been a proposed mechanism with five or more reaction intermediates of which only a certain species may transfer energy to the fluorophore. As the water content of the solvent system increases to that commonly used in HPLC (20–50%, v/v) the chemiluminescence intensity–time profile exhibits only one maximum.

A simplified kinetic model for a comparable system has been described based around the concept of three pools of substances: (A) oxalate, hydroxide, and catalyst; (B) intermediate substances; and (C) products. Pool A reacts with a pseudo-first-order rate constant  $r$  to produce a pool of intermediates (B), which are subsequently converted at a rate constant  $f$  to pool C, as shown in reaction [II]:

The chemiluminescent intensity–time function ( $I_t$ ) can therefore be derived as (eqn [1])

$$I_t = \frac{d(h\nu)}{dt} = \frac{Mr}{f-r}(e^{-rt} - e^{-ft}) \quad [1]$$

where  $M$  is the theoretical maximum intensity for quantitative conversion of reactants into emitting species. This model has been used to determine overall quantum yields of partially aqueous systems.

In spite of these investigations, there is still considerable ambiguity regarding the mechanisms involved. Such studies are hampered by the very nature of the reaction; subtle changes in the oxalate structure, chemical environment, and type of fluorophore can result in large variations in overall quantum yield and emission intensity versus time profiles.

Peroxyoxalate chemiluminescence reactions are analytically important (particularly in HPLC). The most commonly used reagents are bis-(2,4,6-trichlorophenyl)oxalate (TCPO) and bis-(2,4-dinitrophenyl)oxalate (DNPO). Fluorescent compounds (including anthracene, perylene, aminoanthracenes, and aminopyrenes) and suitably derivatized analytes (such as amines, steroids with dansyl chloride; thiols with *N*-[4-(6-dimethylamino-2-benzofuranyl)-phenyl]maleimide and catecholamines with fluorescamine) can be sensitively detected.

Peroxyoxalate chemistry can be used over a wide pH range; TCPO from pH 5 to 9 and DNPO at more acidic values. The more rapid reaction kinetics of DNPO can result in slightly more sensitive assays; however, it is not as stable as TCPO. A major concern with diaryloxalates is the necessity for an organic solvent system owing to their limited aqueous solubility and stability. Common solvent choices have been ethyl acetate/ethanol/water or acetonitrile/water. The requirement to include an organic solvent is a limitation for the determination of hydrogen peroxide generated from oxidase enzymes. Although water-soluble oxamides have been reported with comparable performance to that of TCPO, this class of reagents is not fully evaluated or readily available. The most common application of peroxyoxalate chemiluminescence has been with HPLC for the detection of analytes either exhibiting native fluorescence or those suitably derivatized. Because the fluorophore is not involved in the chemical reaction, it may go through multiple chemiluminescence reaction/excitation/emission cycles to generate several photons per analyte molecule. The lack of source scatter and noise can sometimes give chemiluminescence a sensitivity advantage over fluorescence for the same analyte. Fluorophores such as dansyl derivatives and rubrene can be detected at sub-femtomolar levels with peroxyoxalate chemiluminescence.

## Dioxetanes

Dioxetanes are four-membered cyclic peroxides and their relative stability depends on the types of substituent groups present. Certain 1,2-dioxetanes are stable at room temperature but can be chemically triggered to produce chemiluminescence, these have an adamantyl group on one side of the ring and a

The tautomerism is driven by the increased basic strength of 3-aminophthalate in the aprotic solvent with the resultant structural change decreasing the energy of lowest excited singlet state. The kinetics of the reaction in dimethylsulfoxide are first order with respect to the concentrations of hydroxide, oxygen, and luminol. An important analytical feature is the catalytic effect of certain transition metal cations ( $M^{n+}$ ) upon the reaction shown in **Scheme 4**. The luminescence intensity is proportional to the concentration of species including cobalt(II), copper(II), chromium(III), iron(II), and nickel(II) at levels down to  $\sim 10^{-11} \text{ mol l}^{-1}$ .

Various studies have been conducted on compounds that are structurally similar to luminol with a view to improving the overall quantum yield ( $\phi_{cl}$ ). It was shown that even minor alterations to the heterocyclic ring destroyed the molecules' chemiluminescent property. Thus, compounds such as (3) and (4) showed no chemiluminescence under the reaction conditions outlined in **Scheme 4**.

For the quantum yield to be useful the aromatic ring requires substitution, with 5-position isomers exhibiting significantly higher efficiency than those at the 6-position. The electron-withdrawing ability of the substituent is roughly inversely proportional to the efficiency of light production. This correlation arises from the consequent lowering of the fluorescence quantum yield of the emitting species with the increased electron-withdrawing power of the substituents on the aromatic ring. For example, 5-nitro-2,3-dihydro-1,4-phthalazinedione is  $\sim 10\,000$  times less chemiluminescent than luminol. The knowledge gained from the investigations into the structural aspects of luminol analogs paved the way for the synthesis of compounds such as (5)–(7), which are more chemiluminescent than luminol. However, the relationship between molecular structure and chemiluminescent efficiency is not completely understood, since the bis-dialkylamino derivative (8) is approximately one-third as efficient as luminol.

Despite the numerous and detailed studies concerned with the luminol reaction mechanism, the exact nature of the pathways and intermediates involved are somewhat speculative. However, the most likely starting point appears to be the oxidation of the cyclic diacyl hydrazine moiety to give an azaquinone (**Scheme 6**). In the presence of basic hydrogen peroxide, nucleophilic attack by the hydroperoxide ion would seem most likely; this idea is supported by the luminescence intensity dependence upon hydrogen peroxide concentration. Although there are several possible outcomes from the reaction of the azaquinone with hydroperoxide ion, we shall (for reasons of simplicity) concentrate on that shown in **Scheme 6**.

The mechanism is also consistent with the observation that cyclic diacyl hydrazines are far more chemiluminescent than similar acyclic compounds. The bicyclic peroxide intermediate shown in **Scheme 6** may be precluded by rupture of one C–N bond after the addition of the hydrogen peroxide anion, but before the formation of an anti-aromatic endoperoxide that decomposes to form the emitter. Obtaining hard evidence for the existence of these

**Scheme 6**

intermediate species, whilst problematic, may be feasible with low-temperature nuclear magnetic resonance spectroscopy, since the chemiluminescence from luminol is achievable at temperatures down to  $-50^{\circ}\text{C}$ . This serves to underline the difficulties in relation to the elucidation of chemiluminescent reaction mechanisms.

Luminol is one of the most commonly used liquid-phase chemiluminescence reagents. Oxidants such as permanganate, hypochlorite, or iodine can be used, but hydrogen peroxide is the most common. As previously noted, a catalyst is required with this chemistry and these include transition-metal ions, hexacyanoferrate(III), hemin, and heme proteins (hemoglobin, peroxidases, catalase, and cytochromes). The optimum reaction pH varies between 8 and 11, depending upon the catalyst. This chemistry can be used to sensitively determine the oxidant, catalyst, or species derivatized with luminol or related compounds. It is possible to electrochemically initiate the chemiluminescence reaction of hydrogen peroxide and luminol at an electrode that is held at about  $+0.5\text{ V}$  (versus  $\text{Ag}/\text{AgCl}$ ). The electrode takes the place of the conventional dissolved catalyst. The chemiluminescence reaction is fast enough to confine emission close to the electrode surface. For determination of species labeled with luminol, two electrodes can be used, one at  $-1.0\text{ V}$  to generate the necessary hydrogen peroxide and one at about  $+0.5\text{ V}$  to initiate the chemiluminescence reaction. Detection limits are the same with electrogenerated chemiluminescence as with a conventional dissolved catalyst.

Luminol can be used to derivatize analytes (for immunoassay or HPLC) through substitution at the primary amine but this results in a 10- to 100-fold decrease in chemiluminescence efficiency. Isoluminol (6-amino-2,3-dihydro-1,4-phthalazinedione) is somewhat less efficient than luminol; however, it does not suffer a decrease in efficiency upon binding. Aminobutylethylisoluminol (ABEI, **9**) is a useful precolumn labeling reagent for amines and carboxylic acids because the hydrocarbon spacer isolates the chemiluminophore from the analyte.

Similarly, 4,5-diaminophthalhydrazide (DPH; 6,7-diamino-2,3-dihydro-1,4-phthalazinedione) has been

**Table 1** Comparison of metal ion detection limits with different chemiluminescence systems. All ions have detection limits of  $10\ \mu\text{mol l}^{-1}$  or lower. Ions in bold type have detection limits of  $10\ \text{nmol l}^{-1}$  or lower. Only first-row transition-metal species are considered

used to derivatize aromatic aldehydes,  $\alpha$ -keto acids, and  $\alpha$ -dicarbonyl compounds (Scheme 7).

Certain species significantly increase the chemiluminescence intensity and duration, particularly when horseradish peroxidase is employed as the catalyst. For example, *p*-iodophenol enhances the intensity by more than three orders of magnitude. Enhanced luminol chemiluminescence is advantageously employed for determination of horseradish peroxidase in immunoassay.

Similar to luminol and lucigenin, both lophine and gallic acid also react with alkaline hydrogen peroxide to yield chemiluminescence. In all of these reactions, the emission intensity is proportional to transition metal ion catalyst concentration over finite ranges. Table 1 provides an abbreviated comparison of the selectivity and sensitivity available with these systems.

### Tris(2,2'-bipyridyl)ruthenium(II)

The photoluminescent properties of selected ruthenium(II) *N,N'*-chelates were reported in 1959 and

although the chemiluminescence from tris(2,2'-bipyridyl)ruthenium(II)  $[\text{Ru}(\text{bipy})_3]^{2+}$  (**10**) was observed in 1962, it was not published until 1966. Much of the subsequent research on this compound has focused on the photochemical oxidation of water as a means of solar energy storage and, consequently, knowledge regarding the chemiluminescent reaction mechanisms is limited.

(10)

Chemiluminescence requires the production of tris(2,2'-bipyridyl)ruthenium(III) from the oxidation (chemical or electrochemical) of tris(2,2'-bipyridyl)ruthenium(II). Subsequent reaction with a suitable reducing agent (analyte) elicits light from an excited state of tris(2,2'-bipyridyl)ruthenium(II) (see Scheme 8). This charge transfer luminescence is, in fact, chemically induced phosphorescence (in simple solution) originating from a short-lived  $d\pi^*$  triplet with a lifetime of  $\sim 6 \times 10^{-7}$  s in water and can be regenerated. Excitation is afforded by the promotion of an electron from the  $t_{2g}d^6$  orbital on the ruthenium to the  $\pi^*$  antibonding orbital on the ligand. Intersystem crossing to the triplet state is enhanced by the heavy, paramagnetic ruthenium(II) and the excited state is considered to be a  $d^5 \text{Ru(III)} \text{L}_3^{\bullet-}$ .

The ruthenium(III) chelate is only moderately stable in acidic aqueous solutions and as such it is normally produced immediately prior to reaction. This can be achieved using oxidants such as chlorine, cerium(IV), or lead dioxide. Lead dioxide is a convenient reagent as no excess oxidant remains in solution. The deep green ruthenium(III) complex can also be produced electrochemically, often with the chelate immobilized on a suitable polymer membrane coated onto a working electrode maintained at  $\sim 1.25$  V. In this configuration, the reagent is easily regenerated. The ruthenium(II) complex has been modified and covalently bound onto silica beads to produce a

chemically regenerable form of the reagent. Alternatively, the anhydrous perchlorate salt of tris(2,2'-bipyridyl)ruthenium(III) is temporally stable as a solid or dissolved in dry acetonitrile.

Although a large variety of compounds can reduce tris(2,2'-bipyridyl)ruthenium(III), only certain species (e.g., aliphatic amines, amino acids, NADH, some alkaloids, aminoglycoside or tetracycline antibiotics, and the oxalate ion) will produce the characteristic orange luminescence with this reagent. Subtle differences in chemical structure can have a dramatic effect on chemiluminescence intensity. This is exemplified by the determination of the papaver alkaloid codeine (**11**) compared to structurally similar morphine (**12**). At pH 6.8, codeine can be determined down to a concentration of  $10^{-11} \text{ mol l}^{-1}$ , whereas morphine produces a chemiluminescent response equivalent to that of the blank. In many applications this degree of selectivity is most desirable.

(11)

(12)

The chemiluminescence intensity from the reaction of amines with tris(2,2'-bipyridyl)ruthenium(III) is generally in the order tertiary > secondary > primary, but no definitive mechanisms have been elucidated. Derivatives of tris(2,2'-bipyridyl)ruthenium(II) have been introduced as labels for immunoassay or DNA probes (e.g., (**13**)). The use of chemiluminescent labels is clearly advantageous due to their nonradioactive nature and they can be quantified at sub-picomolar levels via oxidation in the presence of tripropylamine.

(13)

Scheme 8

The reaction with the oxalate anion ( $\text{C}_2\text{O}_4^{2-}$ ) has been extensively studied; most investigations were electrochemical with the reagent and analyte both present in the cell and chemiluminescence observed at a particular oxidative potential. A feasible reaction

pathway has resulted from this considerable body of work. Initially, the ruthenium chelate is oxidized at a platinum or carbon electrode (reaction [III]); subsequent steps are thought to occur in the diffusion layer near the electrode. It is actually the highly reducing radical anion of carbon dioxide that reacts with the Ru(III) form of the reagent to produce the excited state:

## Practical Considerations

Numerous applications involve coupling liquid-phase chemiluminescence detection to physical or chemical separation processes. Conversely, adequate selectivity can also be achieved for particular analytes in a range of sample matrices through a judicious selection of reagent and reaction conditions. Successful detection strategies have been employed for HPLC, flow analysis, electrophoresis, immunoassay labels, DNA probes, and enzyme reactions.

### HPLC and Flow Analysis

Chemiluminescence detectors for HPLC or flow analysis are often custom built and generally incorporate a flat reaction coil situated flush against the window of a suitable photomultiplier tube, as shown in Figure 1.

The distance (and hence volume) between the confluence point of the sample and reagent streams and the detection cell needs to be optimized for the kinetics of the reaction used. The flow cell must be transparent to the wavelength of the chemiluminescence emission and inert to the chemical reaction or solvent system; glass, quartz, and Teflon tubing are commonly employed. Instrumentation for electrogenerated chemiluminescence requires suitable electrodes and a potentiostat to facilitate and control the electrochemistry. Gold, platinum, or carbon working electrodes are placed in the observation cell with counter and reference electrodes situated downstream.

For HPLC, the compatibility between the chemical parameters necessary for efficient separation and sensitive detection is of paramount importance. A compromise between two optima is often required. For example, peroxyoxalate reactions need alkaline conditions but reverse-phase separations (using silica-based stationary phases) require an eluent pH

**Figure 1** Chemiluminescence detection for HPLC or flow analysis using a photomultiplier tube (PMT).

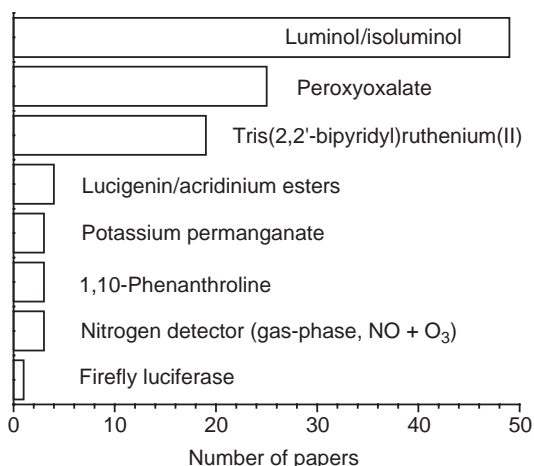

below 6.5. Differences in solvent polarity can also be a problem. Large amounts of water can quench peroxyoxalate emission through reagent insolubility and decomposition.

There has been some investigation into the consumption of immobilized chemiluminescence reagents in flow-through reactors. In flow injection and HPLC, the peroxyoxalate reagent, TCPO, has been used as a packed bed of solid reagent for hydrogen peroxide and fluorophore determinations; the solvent slowly dissolves TCPO from the reactor. Luminol has been immobilized on small particles (silica, nylon, and carbon) contained in flow-through reactors for use in hydrogen peroxide determinations. In all of these schemes luminol is released as required. The TCPO and luminol reactors are eventually exhausted but hundreds of samples can be assayed without the normal requirement of pumping and mixing a separate reagent solution.

Some work has been done with fiber-optic-based chemiluminescence sensors. Luminol has been used with various enzymes immobilized on the end of an optical fiber. Sensors based on electrogenerated chemiluminescence with luminol or tris(2,2'-bipyridyl)ruthenium(II) have appeared; the latter is particularly attractive due the regenerable nature of the reagent. Importantly, for these applications of liquid-phase chemiluminescence, the reactions are occurring at a reactive surface rather than in a homogeneous solution and as such mass transfer probably controls the overall response.

### Capillary Electrophoresis

Since the first publication by Hara and co-workers in 1991, most of the analytically important chemiluminescent reactions have been employed for detection with capillary electrophoresis, as shown in Figure 2. Although chemiluminescence is an attractive mode of detection for capillary electrophoresis, interfacing the detection system with the electrophoretic separation is more complex than with HPLC. Nevertheless, a number of chemiluminescence detectors have been developed and successfully employed for the

**Figure 2** Number of papers that have been published (by mid-2003) on various chemiluminescence reactions used for detection in capillary electrophoresis.

determination of compounds such as amino acids, catecholamines, metal ions, and proteins. The interface design can be categorized as merging flow, coaxial flow, and reservoir mixing, based on the way the chemiluminescence reaction is initiated, or as off-, on-, and end-column based on the site of detection and if it is isolated from the electrophoresis high-voltage supply. Chemiluminescence has also been investigated as a method of detection for microchip-based capillary electrophoresis.

### Enzyme Reaction Products

Coupling chemiluminescence reactions with immobilized enzymes enables the detection of a variety of substrates. A useful example is oxidase enzymes that generate hydrogen peroxide, which can be quantified with several chemiluminescence systems. Substrates including glucose, cholesterol, choline, amino acids, aldehydes, lactate, and uric acid (reaction [IV]) can be determined at the nanomolar level:

This approach can be extended with sequential enzyme steps to ultimately convert an analyte to a desired reagent. In this way, sucrose, maltose, lactose, fructose, glucosides, cholesterol esters, creatinine, and acetylcholine have been measured (reaction [V]):

The most commonly employed system for the determination of hydrogen peroxide under these conditions

is luminol with a peroxidase catalyst. Nevertheless, there are limitations: a high blank signal, interference by other oxidants (O<sub>2</sub>, OCl<sup>-</sup>, O<sub>2</sub><sup>-</sup>), and quenchers present in biological samples. If the solvent and pH requirements of the enzyme are incompatible with reaction conditions, a change after the enzyme reaction will be necessary. There are other enzyme systems (such as  $\beta$ -glucuronidase with glucuronide metabolites, which forms glucuronic acid) that can be detected with lucigenin. Likewise, glucose dehydrogenase reacts with glucose (and NAD<sup>+</sup>) to form NADH, which can be detected with tris(2,2'-bipyridyl)ruthenium(III). After separation by ion chromatography, acetylcholine and choline react with immobilized enzymes to produce hydrogen peroxide, which can be subsequently detected with TCPO and perylene.

### Immunoassay and DNA Assays

A chemiluminescence application that has become much more prevalent and important in recent years is the detection of proteins and oligonucleotides in immunoassay and DNA probe assays (DNA fingerprinting, DNA sequencing, and detection of DNA following electrophoresis and blotting). Nonradioactive labels are of great interest in these areas, and chemiluminescence is an attractive option, owing to advantages of sensitivity (equal to or better than radioactive labels like <sup>125</sup>I), dynamic range, simple instrumentation, long shelf-life, and low cost. In chronological order, the chemiluminescence systems that have found application are luminol, acridinium esters, dioxetanes, and tris(2,2'-bipyridyl)ruthenium(II). The assay can involve either direct labeling with the chemiluminescence species or indirect labeling with a species that catalyzes a chemiluminescence reaction. After incubation (to achieve binding) and then separation of the bound and unbound materials (if necessary), suitable reagents are added to initiate the chemiluminescence reaction. Reagents for a variety of analytes are commercially available.

Direct labels include luminol or aminobutylethylisoluminol, acridinium esters, and tris(2,2'-bipyridyl)ruthenium(II). Luminometers designed for these measurements add the appropriate trigger solution directly in the sample compartment, as the chemiluminescence emission is a short flash lasting from 1 to 5 s. Although one can monitor peak intensity, it is also common to integrate the entire light output. In general, each label molecule reacts only once and will produce only one photon (actually fewer, given the quantum efficiency). An exception to this rule is tris(2,2'-bipyridyl)ruthenium(II), as it can be continuously recycled and re-excited. With acridinium ester labels, the chemiluminescence reaction

results in cleavage of the acridinium ring portion prior to emission. As a result, the labeled material shows the same reaction kinetics and emission properties as the free label.

Catalysts for chemiluminescence reactions can be used as indirect labels, each of which catalyzes the reaction of many substrate molecules and leads to the emission of many photons. For enzyme immunoassay, the most common labels are horseradish peroxidase, alkaline phosphatase,  $\beta$ -galactosidase, and for DNA detection the most common nonisotopic label is alkaline phosphatase. Chemiluminescence systems are available for all these: enhanced luminol for horseradish peroxidase, and dioxetanes for alkaline phosphatase and  $\beta$ -galactosidase. If a sufficiently large concentration of the chemiluminescence reagent is added so that its concentration remains essentially constant during measurement, the rate of the chemiluminescence reaction is limited by the enzyme catalyst concentration. Emission is then in the form of a 'continuous' glow that lasts many minutes to hours and it is no longer necessary for instrumentation or procedures to provide reaction initiation directly in front of detector. Consequently, multiple recordings of emission intensity can be made on microtiter plates or electrophoresis gels. Quantification with enzyme labels generally involves monitoring peak intensity or integration over a fixed time rather than over the entire emission intensity-time profile. As the concentration of the catalyst changes, the rate of reaction changes but the equilibrium position remains constant.

## Gas-Phase

**N W Barnett and P S Francis**, Deakin University, Geelong, VIC, Australia  
**J S Lancaster**, BP Chemicals, Hull, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

The earliest recorded example of chemiluminescence occurring in the gas phase is the oxidation of

phosphorus vapor just above the solid surface by molecular oxygen. Hennig Brandt observed the green emission from this reaction in the seventeenth century. The reaction mechanism is not fully characterized, but the emitting species have been identified as  $(\text{PO})_2$  and  $\text{HPO}$ . Gas-phase chemiluminescence reactions are now known to occur naturally in the upper atmosphere where ultraviolet (UV) radiation produces radicals and ions. Recombination of these reactive oxygen and nitrogen species yields one or

more products in an electronically excited state. Relaxation of the excited state by radiative emission (fluorescence or phosphorescence) completes the sequence of reactions leading to chemiluminescence.

Chemiluminescence reactions generally offer three major advantages in analytical applications: (1) wide dynamic range, (2) low detection limits, and (3) high selectivity. The nitric oxide–ozone reaction, for example, fulfills all these criteria with linearity over six orders of magnitude, detection limits down to low parts per billion ( $\mu\text{g per kg}$ ) or less, and little interference from other species. Gas-phase chemiluminescence reactions have several applications, particularly in the field of atmospheric analysis for nitrogen- and sulfur-containing pollutants, and as a highly sensitive means of detection in gas chromatography (GC). One of the most widely used chemiluminescence reagent gases is ozone ( $\text{O}_3$ ) and we shall begin this review with a discussion on the reaction of ozone with nitrogen compounds, sulfur compounds, and hydrocarbons.

## Chemiluminescence of Nitrogen Compounds

Nitric oxide gives a chemiluminescence emission when reacted with ozone to yield electronically excited nitrogen dioxide (reaction [I]):

This reaction is one of the most well-known and widely used gas-phase chemiluminescence reactions. The emission, which is broadly distributed from 600 to 3000 nm with a maximum intensity at 1200 nm, appears to originate from a combination of the  $^2\text{B}_1$  and  $^2\text{B}_2$  states of nitrogen dioxide. Commercial ozone-mediated nitrogen-specific detectors are fitted with a red filter that allows the emission from excited nitrogen dioxide to pass to the photomultiplier tube while absorbing light from interfering species. To minimize the nonradiative decay of excited nitrogen dioxide molecules, the reaction chamber is operated under reduced pressure, typically 1–100 mmHg.

Detection of compounds other than nitric oxide requires conversion of the analytes (either directly or indirectly) into nitric oxide. The so-called ‘ $\text{NO}_x$  box’ that is frequently used in atmospheric field studies to determine both NO and  $\text{NO}_2$ , requires measurement with and without conversion of  $\text{NO}_2$  to NO by photolysis. Similarly, the ‘total reactive oxides of nitrogen’ can be converted to NO by passing the

**Figure 1** Ozone-mediated chemiluminescence detector. The chromatographic effluent reacts with oxygen or a reagent gas in the furnace. The excited-state species is generated by reaction with ozone, and the emission is detected by a photomultiplier tube (PMT).

sample through a heated molybdenum tube with a catalytically active oxide surface, before quantification with a  $\text{NO}_x$  box. For GC, the conversion of analytes involves a postcolumn reaction. The resulting stream may then be passed through a cryogenic trap to remove less-volatile species, before mixing with ozone in the reduced-pressure reactor. Three commercially available detectors that are based on the nitric oxide–ozone reaction are discussed below. **Figure 1** shows the components of the basic detector.

## Thermal Energy Analyzer

The thermal energy analyzer (TEA) was designed to selectively detect *N*-nitrosoamines, based on their decomposition to nitric oxide (reaction [II]). In this method, the term ‘thermal’ refers to the heat required for decomposition, rather than the mode of detection. A catalyst is often employed to detect a wider variety of compounds at lower temperatures:

The nitric oxide is then determined by its reaction with ozone (reaction [I]). This reaction is specific and can be used for screening purposes without any kind of separation. Alternatively, it can be used as a detector for gas or liquid chromatography where the effluent passes through a pyrolysis chamber and the *N*-nitrosoamines decompose to form nitric oxide. The pyrolysis chamber consists of a quartz or ceramic tube with the catalyst coated onto the walls, or packed into the tube. The most effective catalyst has been found to be a mixture of tungsten oxides.

The temperature of the pyrolysis tube affects the selectivity and must therefore be reproducibly controlled. The nitric oxide radical is cleaved from *N*-nitrosoamines at relatively low temperatures owing to the weak N–NO bond. Cold traps and packed columns of a solid phase such as Tenax are placed between the pyrolysis tube and the detector to remove potentially interfering compounds, while allowing nitric oxide to pass.

*N*-nitrosoamines can undergo pyrolytic decomposition in the absence of a catalyst, to yield nitric oxide, though the required temperature is higher. This can result in a loss of selectivity in the presence of nitro-compounds. The noncatalyzed system is used because of its simplicity in cases where selectivity is less important, for example, in food testing. The TEA is now the detector of choice for the determination of *N*-nitrosoamines in the environment, foods, and tobacco products.

### Nitrogen-Selective Detector

Most nitrogen-containing compounds can be converted to nitric oxide at temperatures between 800°C and 1100°C in the presence of a catalyst. This type of detector, known as a nitrogen-selective detector (NSD) or chemiluminescent nitrogen detector (CLND), is similar to the TEA, except that a stream of oxygen is added to the column effluent before it enters the pyrolysis tube (reaction [III]). Compounds with higher oxidation states of nitrogen are formed in addition to nitric oxide, but at the temperatures employed they thermally decompose to nitric oxide. The nitric oxide is then determined by its reaction with ozone (reaction [I]). Detection limits for the TEA and NSD are  $\sim 1 \times 10^{-12} \text{ mol l}^{-1}$  of carbon-bound nitrogen and the detector response is linear over at least four orders

of magnitude:

### Redox Chemiluminescence Detection

The redox chemiluminescence detector (RCD) is also based on the nitric oxide–ozone reaction. However, unlike the two detectors previously described, the analytes do not contain any oxidizable nitrogen. In this case a nitrogen-containing reagent such as nitrogen dioxide or nitric acid is reduced to nitric oxide by the analyte at a heated gold surface (reaction [IV]):

This detector can therefore be used for any reducing species that can react with nitrogen dioxide, or several oxidized nitrogen species that react with carbon monoxide. Conversion of  $\text{XNO}_2$  compounds occurs rapidly and quantitatively where X is an alkyl, alkoxy, or hydroxyl group and where carbon monoxide is in excess. The formation of nitric oxide is rate limiting and the degree of conversion can be altered by selecting the appropriate catalysts and temperatures. The detector can therefore be made to respond selectively to a particular compound or class of compounds.

A typical gas chromatograph-RCD consists of a nitrogen dioxide inlet, a carbon monoxide inlet, a heated redox reaction zone with a suitable catalyst, and a nitric oxide/ozone reactor for chemiluminescence generation. The RCD, however, has not gained wide acceptance. This may be partly due to the tendency of the gold catalyst to become poisoned and require conditioning with oxygen at high temperature. Table 1 lists some applications of the three

types of chemiluminescence detectors for nitrogen compounds.

## Chemiluminescence of Sulfur Compounds

The oxidation of sulfur monoxide with ozone (reaction [V]) is similar to that of nitric oxide (reaction [I]), but it is more exothermic. The chemiluminescence emission spectrum accompanying this reaction extends from about 260 to 480 nm. At least four excited states of sulfur dioxide are thought to be involved;  $^3B_1$ ,  $^1A_2$ ,  $^1B_1$ , and  $^1B_2$ , which have radiative lifetimes of 8 ms, 30  $\mu$ s, 600  $\mu$ s, and 30 ns, respectively:

This reaction enables the detection of sulfur monoxide and other reduced sulfur compounds that can react with ozone to initially form sulfur monoxide. The chemiluminescence intensity depends on the type of compound, with thiols giving the largest response followed by alkyl sulfides, hydrogen sulfide, and thiophenes. Detection limits in the parts per billion range can be achieved for thiols. Alkenes, which also react with ozone to give emission centered at 354 nm, potentially interfere but selectivity can be achieved with a suitable optical filter.

Universal sulfur-selective detectors for GC or supercritical fluid chromatography (SFC), that incorporate a cool hydrogen-rich flame or closed hydrogen/air burner have been developed and are now commercially available. Combustion products are transferred via a connecting line to a low-pressure reaction cell, where they are mixed with ozone. Although sulfur monoxide is believed to be the common intermediate that reacts with ozone to form the excited sulfur dioxide emitter, it is not necessarily the product of the first conversion step, which has caused debate between instrument manufacturers. One proposed mechanism proceeds as shown in reaction [VI] and it was suggested that the reduced sulfur species could be  $H_2S$ :

Another group ruled out hydrogen sulfide and many other sulfur species as intermediates and tentatively proposed that  $S_3$  forms in the transfer line from

the reaction of sulfur atoms with diatomic sulfur molecules (reaction [VII]):

Sulfur chemiluminescence detectors (SCD) are highly selective; a signal seven orders of magnitude greater than potential interfering species has been reported. In addition, an equimolar response from all sulfur compounds is observed, as the emitter contains only one sulfur atom. These detectors are rapidly becoming the method of choice for the analysis of many sulfur-containing compounds. Furthermore, as nitric oxide is also formed in the SCD and it survives the hydrogen reduction step (reaction [VI]), sulfur and nitrogen can be determined simultaneously. The column effluent can also be split and directed toward an FID, but compromises between the three systems can lead to a reduction in performance.

## Chemiluminescence of Hydrocarbons

Ozone reacts rapidly with alkenes to give a chemiluminescence emission from several excited-state species. Excited species identified as emitters in the ozone oxidation of ethene include formaldehyde at 350–520 nm ( $^1A_2$ ) and hydroxyl radicals at 700–1100 nm ( $X^2\Pi$ ,  $v \leq 9$ ) and 306 nm ( $A^2\Sigma^+$ ). In addition, phosphorescence is observed from glyoxal and methyl glyoxal ( $^3A_u \rightarrow ^1A_g$ ) when substituted alkenes are oxidized.

Alkanes and aromatic compounds are less readily oxidized than alkenes, but can be made to react with ozone at higher temperatures to give a chemiluminescence emission. This difference in reactivity can be exploited to increase selectivity. For example, a postcolumn reactor at 100°C allows only the detection of alkenes, but when the temperature is increased to ~150°C aromatic compounds will also elicit chemiluminescence and at 250°C all other hydrocarbons will give rise to emission. Aromatic compounds are likely to react in a similar way to alkenes, by forming an ozonide intermediate. The reaction pathway for the ozone-mediated chemiluminescence of alkanes is unknown and results in much lower chemiluminescence intensity. The detector response is linear when ozone is present in excess and absolute

detection limits for alkenes are reported to be in the nanogram range.

## Other Reactions with Ozone

The concentration of nickel carbonyl in air can be determined using the chemiluminescence reaction with ozone and purified carbon monoxide (reaction [VIII]). The emission intensity is measured at  $\sim 500$  nm and the detection limit is 2 ppbv:

The reaction between ozone and arsine leads to an emission continuum in the visible region and a discrete emission in the UV. The hydrides of arsenic, antimony, and tin can be determined down to sub-ppb levels. The chemiluminescent reaction between ozone and phosphine has been employed to determine phosphate and other phosphorus-containing compounds after reduction. The chemiluminescent oxidation of silane was used to determine silicate in natural waters. A variety of applications involving ozone as a reagent gas have been included in Table 2.

## Flame Photometric Detector

Chemiluminescence emission may occur in cool flames at temperatures below that required for thermal excitation. This is the basis of the flame

photometric detector (FPD). An example of this is the molecular emission of sulfur in cool ( $<1000^\circ\text{C}$ ) hydrogen-rich flames. Sulfur atoms are formed in the flame and recombine to form electronically excited  $\text{S}_2$  ( $\text{B}^3\Sigma_u^-$ ), which emits a photon to return to the ground state ( $\text{X}^3\Sigma_g^-$ ), as shown in reaction [IX], where M is another atom or molecule. The reaction forming the emitter is second order with respect to sulfur atoms and therefore the signal has a quadratic dependence on analyte concentration:

Organophosphorus compounds can also be detected; they react to give excited HPO. The same detector can be made selective to phosphorus and sulfur-containing species by using the appropriate optical filters with dual photomultipliers. Emission from the excited  $\text{S}_2$  molecule is monitored at 394 nm and that from HPO at 526 nm. This detector is subject to quenching and analyte dependency. Two flames can be used to separate the region of sample decomposition and excitation. The first flame breaks down large molecules in the column effluent into smaller fragments that reportedly do not quench the emission. The excited-state sulfur and phosphorus species are formed in the second flame. The dual flame design results in greatly improved selectivity with respect to hydrocarbons. Selectivity ratios reported for phosphorus and sulfur are of  $10^{-5}$  and up to  $10^{-6}$ , respectively.

Although determinations of sulfur and phosphorus compounds constitute the main applications of the FPD, there are  $\sim 20$  emitters that produce analytically useful signals. Nitrogen-containing

SCD, sulfur chemiluminescence detector; PFPD, pulsed flame photometric detector; FPD, flame photometric detector.

organic compounds react in an analogous manner to phosphorus, to form excited HNO, which emits at  $\sim 690$  nm. Compounds containing manganese or ruthenium exhibit photon yields (from  $\text{Mn}^*$  and an unknown emitter) that are comparable with those of sulfur and phosphorus. Iron compounds produce a rich spectrum of atomic lines from  $\text{Fe}^*$  at a temperature of only  $346^\circ\text{C}$ . Selenium and tellurium compounds, like those of sulfur, produce diatomic emitters ( $\text{Se}_2^*$  and  $\text{Te}_2^*$ ) and therefore a nonlinear relationship between concentration and intensity is observed.

The pulsed FPD (PFPD) is an improved FPD that was developed during the past decade. The PFPD uses a pulsed flame and time-resolved emission detection, which in addition to providing greater selectivity, has substantially improved the overall performance. This sensitivity of this multianalyte detector is similar to those specifically designed for nitrogen/sulfur chemiluminescence, but the selectivity for nitrogen and sulfur over hydrocarbons is still much lower. This approach has been extensively applied to organotin and organophosphorus compounds. GC-PFPD can be coupled with mass spectrometry to provide even greater information. Some applications of PFPD are shown in Table 2.

## Other Reagent Gases

### Molecular Fluorine

Fluorine reacts with certain organosulfur compounds to generate excited-state species via an unknown pathway. The reaction is highly exothermic owing to the fission of the very weak F–F bond, and the formation of strong H–F and C–F bonds. This is the basis for a highly selective chemiluminescence detector for reduced sulfur compounds. The chemiluminescence emission in the red and near-infrared is due to the formation of vibrationally excited hydrogen fluoride. The fluorine chemiluminescence detector (FCLD) has been successfully interfaced with GC, high-performance liquid chromatography (HPLC), and SFC, and shown to be analytically useful for thiols, sulfides, disulfides, and thiophenes, with detection limits in the low picogram range. Thiophenes are rather less reactive owing to the stability imparted by their aromaticity, and their detection limits are an order of magnitude poorer. The detector response is linear in most cases over more than three orders of magnitude. This detector has also been used for organotellurium and organoselenium compounds, phosphines, alkyl phosphines, and phosphinate esters.

### Atomic Fluorine

Atomic fluorine can be generated by microwave discharges in  $\text{F}_2$ ,  $\text{CF}_4$ , or  $\text{SF}_6$ . Chemiluminescence from the reaction of fluorine atoms with hydrocarbons is almost universal and results from the production of vibrationally excited HF via hydrogen abstraction. Although the HF overtone band at 880 nm can be used to detect many species that contain hydrogen, this reaction also generates chemiluminescence from  $\text{C}_2$  and CH at 470 and 431 nm, respectively, which provides selective detection of hydrocarbons. Other classes of compounds can be selectively monitored. For example, iodo compounds react to produce excited IF, which has been monitored at 580 nm, with reported detection limits of  $\sim 1$   $\mu\text{g}$ .

### Atomic Oxygen

Oxygen atoms are more powerful oxidants than ozone, and produce chemiluminescence with a wide range of analytes. Nevertheless, the analytical application of this reagent is very limited. One reason for this is that the five different excited states of molecular oxygen formed in the recombination of oxygen atoms (reaction [X]) produce a background emission across the entire visible region that increases quadratically with oxygen atom concentration:

The reaction between oxygen atoms and nitric oxide produces a continuum between 400 and 1400 nm from excited nitrogen dioxide. These are significantly lower wavelengths than those of the previously discussed reaction between nitric oxide and ozone. This reaction has been used to determine oxygen atoms in kinetic experiments. As with the oxidation of sulfur monoxide with ozone, oxidation with oxygen atoms produces sulfur dioxide in electronically excited states. In this case, the emission is distributed from 240 to 400 nm with a maximum at  $\sim 270$  nm.

### Active Nitrogen

Passing molecular nitrogen ( $\text{X}^1\Sigma_g^+$ ) through a microwave or electrical discharge produces ‘active nitrogen’, which is a cool plasma of atoms ( $^4\text{S}$ ) and excited molecules ( $\text{A}^3\Sigma_u^+$  and  $\text{B}^3\Pi_g$ ). These nitrogen species undergo collisional energy transfer with saturated hydrocarbons, leading to excited states of these species. In addition, the active nitrogen can undergo a variety of abstraction and addition reactions with unsaturated molecules, resulting in excited-state cyanogen radicals. This is the basis

for a universal chemiluminescence response to hydrocarbons. Detection limits in the nanogram range have been reported for saturated hydrocarbons, whilst for unsaturated analytes detection limits approaching 100 pg have been reported. Compounds other than hydrocarbons (including organometallics, halogens, and compounds containing oxygen, phosphorus, or sulfur) can be detected by monitoring different emitters. Organometallic compounds have been shown to produce excited metal species in addition to cyanogen radicals, and by monitoring the characteristic atomic emission line of the metal of interest some selectivity can be achieved.

### Atomic Sodium

Atomic sodium, generated by heating the metal to 400°C, has been used for the specific detection of halocarbons containing more than one halogen atom in a low-pressure postcolumn reactor. The reaction pathway leading to chemiluminescence is thought to involve abstraction of the halogen atoms to form excited sodium halide and an alkene. Collision between the excited sodium halide (NaX) and another sodium atom produces a doublet sodium atom (reaction [XI]), which can emit at 589 nm (i.e., the sodium D-line). Detection limits in the low picogram to high femtogram range have been reported for chlorinated and brominated compounds, but fluorinated compounds are much less sensitive owing to the strong C–F bond:

### Chlorine Dioxide

Chlorine dioxide is a highly selective chemiluminescence reagent for two sulfur compounds: hydrogen sulfide and mercaptoethanol. The exact reaction pathway is unknown, although it is thought that sulfur atoms produced in the reaction recombine to form excited S<sub>2</sub> molecules, as in the FPD. A detection limit of 3 µg l<sup>-1</sup> hydrogen sulfide has been quoted.

### Official Methods

Several American and British official analytical methods (ASTM, BSI) and Environmental Protection Agency (EPA) recommended procedures for monitoring industrial and environmental samples utilize

gas-phase chemiluminescence detection. These methods include the trace analysis of nitrogen-containing species in liquid petroleum hydrocarbons, the atmospheric monitoring of ozone by measurement of the chemiluminescence emission due to the ozone oxidation of ethene, and a standard assay for chemically bound nitrogen in natural waters. Most process analyses for the measurement of nitrogen oxides in gaseous effluent streams utilize gas-phase chemiluminescence detection.

### Introduction

Although the application of chemiluminescent phenomena to various analytical problems is well established, electrogenerated chemiluminescence as an analytical tool has been developed relatively recently. In electrogenerated chemiluminescence (ECL) one or more of the reagents is generated *in situ* in an electrolytic process. ECL shares many analytical advantages with chemiluminescence, the most important one being the low detection limit owing to the low background emission. This article will briefly review the working principles outlined in the most important publications on analytical assays based on ECL and their application areas.

### Electrochemiluminescent Systems

As in conventional chemiluminescence, the change in free energy of the reaction leading to the emitting species needs to be of the order of  $200 \text{ kJ mol}^{-1}$  in order to produce emission in the visible range. This, together with the structural demands on the emitting species makes chemiluminescent reactions rather rare. Methods based on ECL have the advantage, however, that electrolytic processes are capable of producing highly energetic, although unstable, reactants not easily produced through any other chemical means, so that the high energy demands of chemiluminescence may be met. In most cases at least one of the reactants of any chemiluminescent system can be generated electrochemically, and hence ECL is actually more generally applicable than chemiluminescence.

#### Aromatic Radical Ion Annihilation

Reactions between oppositely charged aromatic or heteroaromatic radicals are among the most thoroughly studied electrochemiluminescent reactions. These reactions, which are carried out in aprotic solvents, can be generally written as in reactions [I–V],

or

Here singlet and triplet states are denoted by the left superscripts 1 and 3, respectively. In the first case the reaction is energy sufficient, i.e., the change in free energy of the reaction is high enough to generate the excited singlet state directly in one step. In the latter case the reaction is energy deficient and the first step [III] generates the lowest triplet state. The emitter is then generated by triplet–triplet annihilation [IV]. The radical cations and anions are generated either at a single electrode by applying alternate positive and negative pulses or at two separate closely spaced electrodes. The species R and S may be the same or different. Typical examples are anthracene, 9,10-diphenylanthracene, *N,N,N',N'*-tetramethyl-*p*-phenylenediamine, rubrene, and pyrene.

From the analytical point of view the luminescent annihilation of aromatic radicals suffers from the detrimental effect of oxygen and protic solvents, especially water. In fairly well-controlled conditions the system has been used as a basis for a selective liquid chromatographic detector, although the advantages compared with, for example, fluorometric detection are not apparent.

#### Platinum Metal Chelates

Some platinum metals, especially ruthenium but also rhenium, osmium, and iridium, form luminescent complexes with nitrogen-containing ligands, e.g., 2,2'-bipyridine (bpy). These complexes may participate in redox reactions with concomitant chemiluminescence in three different ways.

(a) Annihilation reactions in aprotic media, e.g., for tris(2,2'-bipyridyl)ruthenium(II),  $\text{Ru}(\text{bpy})_3^{2+}$  ((1), Figure 1); see reaction [VI]:

(1)

(2)

(3)

**Figure 1** Three typical electrochemiluminescent compounds: (1) tris(2,2'-bipyridyl)ruthenium(II),  $\text{Ru}(\text{bpy})_3^{2+}$ ; (2) luminol; and (3) 2,6-bis(*N,N*-bis(carboxymethyl)aminomethyl)-4-benzoylphenol.

These reactions are analogous to the annihilation reactions of aromatic compounds and suffer from the same drawback, namely the sensitivity to water.

(b) Oxidation–reduction mechanisms (ox–red) where a substrate (co-reactant) *S* is initially oxidized directly at the electrode or through a reaction with  $\text{Ru}(\text{bpy})_3^{3+}$ , forming a strong reductant *R* that reacts with the ruthenium complex, generating light

(reaction [VII]):

A typical substrate *S* is oxalate, where *X* is then  $\text{CO}_2$  and  $\text{R}^\bullet$  is the anion radical  $\text{CO}_2^{\bullet-}$ . Even more efficient than oxalate are tertiary amines. It has been recently shown that the cation radical produced by tripropylamine by one-electron oxidation is a stronger oxidant than  $\text{Ru}(\text{bpy})_3^{3+}$  and has a rather long lifetime in aqueous solution at an appropriate pH value prior to deprotonation-induced redox inversion to a strongly reducing radical. Thus this cation radical can serve as an oxidizing mediator reaching  $\text{Ru}(\text{bpy})_3^{2+}$  species at quite long distances from the electrode surfaces. This is very useful when  $\text{Ru}(\text{bpy})_3^{3+}$  derivatives are used as electrochemiluminescent labels in binding assays carried out on the surfaces of magnetic latex beads that are finally collected by applying magnetic field on the working electrode during the detection step of the assay.

(c) Reduction–oxidation mechanisms (red–ox) where a substrate *S* is first reduced, forming a strong oxidant  $\text{R}^\bullet$  (reaction [VIII]). Normally, a substrate cannot undergo a one-electron reduction at an active metal electrode, and therefore, only the reduction by  $\text{Ru}(\text{bpy})_3^+$  is typically significant:

A typical substrate is the peroxodisulfate ion, with *X* being the sulfate ion and  $\text{R}^\bullet$  the sulfate radical  $\text{SO}_4^{\bullet-}$ .

In contrast with (a), the reactions in (b) and (c) also take place in protic media. The quantum yield of these ECL processes is rather high, and consequently the analytical methods based on these reactions have a very low detection limit. The most promising applications of these compounds are as labeling compounds in the ECL binding assays, i.e., immunoassays and DNA probe assays.

### ECL of Conventional Chemiluminescent Compounds

Many chemiluminescent reactions are based on hydrogen peroxide as a co-reactant. One of

these reactions is the oxidation of luminol (3-aminophthalhydrazide (2), **Figure 1**). In this reaction luminol reacts with hydrogen peroxide in the presence of catalysts, generating light. There are a large number of analytical methods for either hydrogen peroxide or catalysts based on this reaction. Hydrogen peroxide can also be generated electrolytically, and in fact, the oldest reported ECL reaction is based on this.

Some analytical methods, for example, for detection of trace metals, have been devised based on this reaction. Luminol has also been suggested as a labeling compound for the ECL immunoassay. In addition to luminol there are a number of analogous chemiluminescent compounds that require hydrogen peroxide in their luminescent reactions. Among these compounds the acridine derivatives lucigenin and acridinium esters have been used in ECL methods.

### ECL at Thin Insulating Film-Coated Electrodes

Emission of light from valve metal or semimetal electrodes (e.g., aluminum, magnesium, zirconium, tantalum, silicon) is observed when current is flowing in either direction through the interface between the electrode and the electrolyte solution during AC or pulsed excitation. The intensity and spectrum of the cathodic emission depends on the composition of the contacting electrolyte solution. Cathodic ECL is induced by certain metal cations, either complexed or uncomplexed, and organic fluorescent compounds. In most cases the presence of a co-reactant, a compound that is electrolytically reduced to a strongly oxidizing agent, is needed, e.g., peroxodisulfate ion or oxygen. The cathodic ECL at thin insulating film-coated electrodes can be obtained using cathodic potential pulses either with precoated electrodes (e.g., silicon electrodes coated with high-quality thermal oxide films) or using anodically oxidizable valve metal electrodes that are oxidized *in situ* during the ECL measurement through anodic potential pulses, yielding insulating surface films. Those anodic metal oxide films that behave as n-type semiconductors (e.g., tantalum oxide) cannot be utilized this way in most applications, and only those wide band gap oxide films having their Fermi level in the midgap region are generally usable. However, semiconducting oxide films can also offer an interesting basis for analysis when they are doped with luminescent metal ions and are used to probe hydrogen peroxide or clinical analytes, which are enzymatically coupled with their production.

The primary step of cathodic ECL at thin insulating-film coated electrodes is hot electron injection into the electrolyte solution using tunnel emission,

which is also called direct field assisted tunneling. The insulating film at the electrode must be ultrathin, i.e., its thickness must be of the order of 4 nm.

In contrast to traditional electrochemistry at active metal electrodes, one-electron reductions in aqueous solutions can be easily carried out at thin insulating film-coated cathodes and in the reduction potential range not obtainable at active electrodes. For instance, even toluene (R) can be excited in aqueous solution/emulsion through hot electron injection at thin insulating film-coated electrodes by the following ox-red mechanism:

A pulsed voltage waveform is normally used for the excitation. A large number of organic fluorescent compounds produce ECL at thin insulating film-coated electrodes in aqueous solutions, providing an alternative excitation method to photoluminescence. Some weak background emission is also observed without any luminescent additives during cathodic pulses due to high electric field-induced solid state electroluminescence from the insulating oxide films. By using excitation with short cathodic pulses and compounds displaying long-lived luminescence, the effect of this background can be largely eliminated.

### Instrumentation

The apparatus for making ECL measurements comprises the following main parts (**Figure 2**).

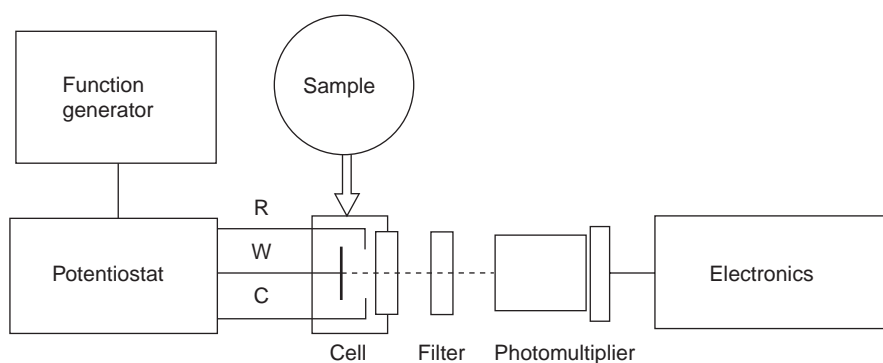

#### Function Generator

In most cases the excitation waveform in ECL is a periodic signal, often consisting of rectangular pulses with a variable duty cycle, or a sawtooth signal (**Figure 3**). For research purposes the function generator should preferably be programmable to allow easy generation of different voltage waveforms.

#### Potentiostat

The potential of the working electrode is controlled by means of a potentiostat. In some applications, a real reference electrode is not necessary and it is sufficient to use a pseudo-reference electrode or even to use the counter-electrode as a pseudo-reference electrode. In the latter case, only the voltage between the working electrode and counter-electrode is controlled, i.e., the real working electrode potential is reproducible only if the properties of the

**Figure 2** Schematic diagram of ECL detection system. W, working electrode; R, reference electrode; C, counter-electrode.

**Figure 3** Examples of voltage excitation waveforms and resulting luminescence signals in ECL measurements. (A) Symmetrical double-step waveform used in, e.g., ECL measurements with valve metal electrodes. (B) The sharp cathodic pulse and resulting signal in time-resolved ECL measurements with e.g., Tb(III) complexes. The shadowed region of the signals in (A) and (B) is integrated on a gated integrator. (C) Sawtooth waveform and resulting signal used, e.g., in ECL measurements with ruthenium complexes at active metal electrodes.

electrochemical cell remain unchanged between separate measurements.

### Electrochemical Cell and Electrodes

The design of the electrochemical cell depends on the method of application. In general, the cell contains two or three electrodes and an optical window. Platinum is the most commonly used material for the working electrode, although glassy carbon and gold have also been used. In some cases the electroluminescent material is immobilized in a Nafion perfluorinated ion exchange polymer film coated on the surface of a platinum or carbon electrode. In methods using oxide-coated electrodes, aluminum, silicon, zirconium, and tantalum are the materials mostly used. Often a rotating disk electrode is used as a working electrode, especially when the mechanism of ECL is being studied.

### Sample Introduction

The ECL measurement is carried out as a simple batch measurement or alternatively in a liquid stream. In the first case a spike of the analyte is added to the appropriate electrolyte solution, the solution is transferred to the cell, and the ECL signal is recorded. In the latter case, the sample is injected into the flowing liquid, which transfers it to the ECL cell either with (e.g., liquid chromatography (LC)) or without (flow injection analysis) a separation step.

### Detector

The intensity of ECL is in most cases so low that the most sensitive light detector, a photomultiplier tube (PMT), is necessary. Also avalanche photodiodes have been developed for photon counting purposes, and they can be expected to compete successfully with PMTs in the future, especially in miniaturized analytical systems. Depending on the application, the

detecting device may be preceded by an optical filter but in analytical applications hardly ever by a monochromator.

### Electronics

The electronic circuitry used depends on the method of measurement. At low light levels photon counting allows better discrimination against the noise than does analog recording. Both these methods have been used, although one can anticipate that with the continuous decrease in the cost of electronics photon counting will eventually win. The only instrumental advantage of analog recording of the photomultiplier anode current is better linearity at high light levels owing to the pulse pile-up in photon counting. In the time-resolved measurements the detection circuit is synchronized with the excitation pulses, allowing a fixed or variable time delay between the pulse and the recording window (Figure 3B).

### Analytical Applications

Electrochemiluminescence offers an alternative method of luminescence excitation. Its advantages as an analytical method compared with photoluminescence are partly the same as with chemiluminescence:

1. No expensive excitation optics is needed. Electronic excitation requires comparatively simple and inexpensive instrumentation.
2. Electrochemiluminescent reactions are quite rare. Although this may be a drawback if general methods are sought for, it is clearly an advantage if the electroluminescent compound is used for labeling, because of the smaller likelihood of interference.
3. ECL is often confined to the surface of the electrode or its close vicinity. Reactive intermediates generated by the electrode processes are often very short lived, and the action distance from the surface toward the bulk solution is small. This feature can be exploited, for example, in developing methods for homogeneous immunoassay.

One disadvantage of ECL methods is the frequent fouling of the electrodes. This effect can sometimes be prevented by regular electrochemical cleaning of the electrodes. In the case of an inexpensive electrode material such as aluminum, or even silicon manufactured in large quantities, the electrode is disposable.

### Inorganic Ions

Ruthenium can be determined down to subpicomolar level by complexing with suitable ligands, e.g., bpy, and applying ECL measurement. For example, various concentrations of  $\text{Ru}(\text{bpy})_3^{2+}$  are added to a solution of  $18 \text{ mmol l}^{-1} \text{ Na}_2\text{S}_2\text{O}_8$  and  $0.1 \text{ mol l}^{-1} \text{ Bu}_4\text{NBF}_4$  in acetonitrile–water (1:1, v/v) and the ECL emission is measured after deaeration. The logarithm of the light intensity is linear with the logarithm of concentration over six orders of magnitude from  $10^{-13}$  to  $10^{-7} \text{ mol l}^{-1}$ . Using tripropylamine instead of peroxodisulfate, linearity extending up to seven orders of magnitude can be achieved. The method may equally be used for the determination of peroxodisulfate and oxalate. For instance, oxalate can be determined by its chemiluminescent reaction with  $\text{Ru}(\text{bpy})_3^{3+}$  in the concentration range  $10^{-6}$ – $10^{-4} \text{ mol l}^{-1}$ . This happens to encompass the concentrations found in normal human blood and urine. Luminol-based ECL has been used for the determination of trace concentrations of cobalt(II) and copper(II), based on the fact that these metal ions effectively catalyze the luminescent reaction between luminol and electrogenerated hydrogen peroxide.

Certain metal ions in aqueous solution in the presence of hydrogen peroxide can be determined using ECL with a rotating aluminum disk electrode. With the uncomplexed metal ions the lowest detection limit ( $10^{-10} \text{ mol l}^{-1}$ ) is achieved with thallium(I), but mercury(II), copper(II), lead(II), and silver(I) induce relatively intensive ECL allowing detection in trace quantities. From the analytical point of view the most important metal ions determined at an oxide-covered aluminum electrode are europium(III) and terbium(III). Terbium, when complexed with 2,6-bis(*N,N*-bis(carboxymethyl)aminomethyl)-4-benzoylphenol ((3), Figure 1) or other ligands of analogous structure can be determined down to subpicomolar levels at stationary oxide-coated aluminum and silicon electrodes in the presence of potassium peroxodisulfate. The linear range of the log–log plot of emission intensity versus concentration of terbium is in these cases from  $10^{-12}$  to  $10^{-6} \text{ mol l}^{-1}$ . It should be noted that the luminescence lifetime of this terbium complex is  $\sim 2 \text{ ms}$ . The lifetime of the background solid state cathodic electroluminescence originating from the oxide film is much shorter, which allows time-resolved resolution of the analyte signal from the background. Determination of these metal cations is not important *per se* but is important in connection with the development of labeling compounds for binding assays (see below). Aromatic lanthanide(III) chelates ( $\text{Ln(III)}$ ) can be electrochemically excited in aqueous solutions only at thin

**Table 1** Examples of organic compounds determined using ECL

Compound	Method	Compound	Method
Luminol	a	Salicylic acid	c

a, conventional chemiluminescence with electrogenerated  $\text{H}_2\text{O}_2$ ; b, radical ion annihilation; c, ECL on an oxide-covered aluminum electrode in the presence of  $\text{K}_2\text{S}_2\text{O}_8$ ; d, as a co-reactant in the ECL of a ruthenium–bipyridine complex.

insulating film-coated electrodes through hot electron chemistry. The excitation occurs through the so-called ligand-sensitized mechanism, in which the ligand is first excited by the above-mentioned ox–red or red–ox excitation pathway and then energy is transferred from the ligand intramolecularly to the central Ln(III) ion, which finally emits through its typical sharp-peaked f-shell radiative transitions, having relatively long luminescence lifetimes (up to  $\sim 2.2$  ms).

### Organic Compounds

The organic analytes that can be determined using ECL belong to two groups: (1) compounds or their reaction products that are luminescent; (2) compounds that participate in the chemiluminescent reaction without being luminescent *per se*. A representative list of organic compounds belonging to each group along with the method of measurement is shown in Table 1.

Polycyclic aromatic hydrocarbons (PAHs) belong to the group of compounds that in principle can be determined directly using ECL with the radical annihilation method. One practical drawback making the quantitative assay difficult is the sensitivity of the method to water and oxygen. However, ECL has been used as a detection system for reversed-phase LC with a mobile phase containing 10–20% water. ECL with oxide-coated electrodes has been used for the PAH assay in a micellar aqueous phase.

If an organic compound is fluorescent and reasonably soluble in water (or in a micellar aqueous phase), it most probably produces ECL at thin insulating film-coated electrodes in the presence of peroxodisulfate or oxygen. For instance, salicylic acid can be determined with a linear range of  $10^{-8}$  to  $10^{-4} \text{ mol l}^{-1}$  at a rotating oxide-covered aluminum

electrode, and e.g., aminonaphthalene sulfonates, fluorescein, eosine, and some coumarins have detection limits of  $\sim 10^{-10}$ – $10^{-9} \text{ mol l}^{-1}$  at oxide-covered stationary aluminum electrodes.

Ruthenium complexes need a strong reductant or oxidant for chemiluminescent reactions of type (b) and (c) above. These reactive compounds are usually radicals derived from simple organic compounds such as amines, amino acids, the reduced form of  $\beta$ -nicotinamide adenine dinucleotide (NADH), and some antibiotics. Analytical procedures have been developed for some of these compounds on this basis, e.g., for tripropylamine, which gives a detection limit of  $\sim 2 \times 10^{-8} \text{ mol l}^{-1}$ .

### Hydrogen Peroxide

Hydrogen peroxide is produced in various enzymatic reactions, and its determination is the basis for a number of assay methods. A direct ECL method is based on the use of tantalum or zirconium electrodes covered with a terbium(III)-doped oxide layer. Light with the typical emission spectrum of terbium(III) is emitted from the surface of the electrode in the presence of hydrogen peroxide.

In indirect ECL methods, hydrogen peroxide is generated electrolytically at a negatively biased glassy carbon or gold electrode and detected through the chemiluminescence of, e.g., luminol. Hydrogen peroxide is transported by a liquid flow toward the chemiluminescent reagent and during this time is partially decomposed by the sample molecules, which act as a catalyst. The sample could be, for instance, heme components, which effectively catalyze the decomposition of hydrogen peroxide.

### ECL Labels

Labeling techniques are used extensively in immunoassays and DNA probe assays. The label molecules

have a certain distinct feature, e.g., a radioactive atom or fluorescence, that allows detection and quantification at a very low concentration level. The use of labels based on detection using ECL has advantages in certain applications. In ECL the emission source is a very narrow zone in the close vicinity of the electrode. If in the binding assay one of the reactants is immobilized on the electrode, then complexation with the labeled molecule brings the ECL label close to the electrode, where it is effectively excited. This makes the nonseparation or 'homogeneous' binding assays possible. Another factor favoring ECL compared with fluorescence is its simpler and less expensive excitation technique. Immunoassays based on ECL of luminol and ruthenium complexes as well as ECL at oxide-covered electrodes have been demonstrated. For example, assays for the important thyroid-stimulating hormone (TSH) have been developed based both on ruthenium labels on a gold electrode and terbium labels on disposable oxide-coated aluminum and silicon electrodes. Both methods give a reasonably linear calibration line for TSH in the clinically important concentration range. One of the benefits of hot electron-induced cathodic ECL at thin insulating film-coated electrodes is that luminophores having very different optical and redox properties can be simultaneously excited. Thus, e.g., Tb(III) chelates, Ru(bpy)<sub>3</sub><sup>2+</sup>, metalloporphyrins, luminol, fluorescein, and many other fluorescent labeling compounds can be excited simultaneously in multiparametric assays. In addition, the signals from different types of label compounds emitting in the ultraviolet, visual, and near-infrared ranges can be separated from each other either by wavelength discrimination or by time discrimination or even by their combination. Some phosphorescent metalloporphyrin labels can be alternatively used instead of Ln(III) chelate labels when long-lived ECL displaying labels are required.

## Introduction

In the analytical sciences it is usual to make a fairly small number of measurements on a given material. This small dataset in statistical terms constitutes a sample. Because of random errors the replicate values within the sample will not be identical, but the analyst must provide an estimate of these errors – without such an estimate the quantitative results presented would be meaningless. Statistics provides the means to do this by estimating the results that would have been obtained if a hypothetically infinite population of measurements had been made. This distinction between samples and populations is fundamental: results relating to samples are given English symbols (e.g.,  $\bar{x}$  for a sample mean), whereas those describing populations are given Greek symbols (e.g.,  $\mu$  for a population mean). The link between samples and populations is generally made by assuming that the data come from a population with a specific frequency distribution.

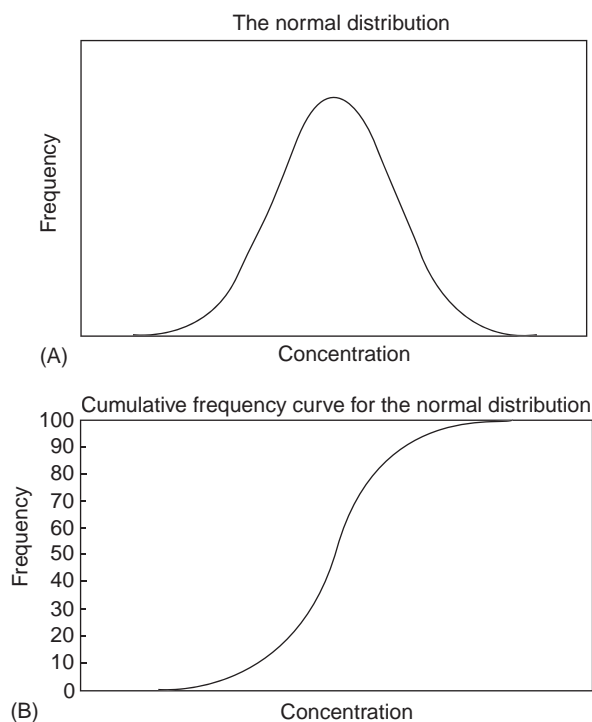

## The Normal Distribution

When replicate analyses of the same material are made in the same experimental conditions it is usual to assume that the frequency distribution of the results is a normal or Gaussian one. This distribution

has the mathematical form:

$$y = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2} \quad [1]$$

where  $y$  is the frequency with which a given value of the measurement  $x$  occurs. The normal distribution has the form shown in **Figure 1A**. The exact shape of the curve is defined by the parameters  $\mu$  and  $\sigma$ , which are the mean and standard deviation of the population, respectively, and describe the position of the curve (the  $x$ -value at which the frequency is maximal – this is the population mean,  $\mu$ , because the curve is

**Figure 1** The normal (Gaussian) distribution represented as (A) a frequency curve: and (B) a cumulative frequency curve.

symmetrical) and its width (see below). An alternative representation of the normal distribution is the cumulative frequency curve, shown in **Figure 1B**. In this case, the y-axis gives the frequency, on a scale of 0–1% or 0–100%, of any value of  $x$  and all the lower values of  $x$ . The cumulative frequency reaches 0.5% or 50% at the mean value of  $x$ , i.e., the maximum of the frequency plot in **Figure 1A**.

**Figure 2** shows the outcome of a Microsoft Excel® simulation of 100 values of the nitrate ion concentration in a single water sample (ppm). It is most unlikely that any material would actually be analyzed 100 times, but the data are used to demonstrate methods by which such results are presented. Each result is given to two places of decimals, all the results lying in the range 0.43–0.57 ppm. The ‘Frequency’ column in the spreadsheet shows the number of times that each value 0.43, 0.44, 0.45, ..., 0.57 occurs, and this column along with its neighbor headed ‘Value’ comprises a frequency table. The data in this table can be plotted as a bar chart, as shown in **Figure 2**. The shape of this bar chart is approximately the same as the smooth ideal curve for the normal distribution shown in **Figure 1A**. An additional column shows the cumulative frequency values, and when these are plotted as a bar chart the curve obtained looks similar to that in **Figure 1B**. The bar chart, frequency table, and cumulative frequencies are just three of several ways in which replicate experimental data can be presented.

Using eqn [1] it can be shown that ~68% of the measurements in a normal population lie within  $1\sigma$  of the mean value,  $\mu$ , i.e., between  $\mu - \sigma$  and  $\mu + \sigma$ . Ninety-five percent of the measurements fall in the range  $\mu \pm 1.96\sigma$  often approximated as  $\mu \pm 2\sigma$ , and 99.7% of the measurements in the range  $\mu \pm 3\sigma$ . This is equivalent to saying that 68% of the area under the curve lies between  $\mu - \sigma$  and  $\mu + \sigma$  and so on). These multipliers of  $\sigma$ , i.e., 1 for 68% of the results and 1.96 (for 95%), are examples of the statistic  $z$ , which can be used to express any value of  $x$  in terms of its deviation from the mean in standard deviation units, i.e.,

$$z = \frac{x - \mu}{\sigma} \quad [2]$$

These properties of the normal distribution are of great importance, as they are used to calculate confidence intervals and limits (see below).

In practice, when a sample of measurements is studied, it is necessary to estimate the value of  $\mu$  using the sample mean,  $\bar{x}$ :

$$\bar{x} = \sum_{i=1}^n x_i / n \quad [3]$$

the  $x_i$  values being the  $n$  individual measurements. An alternative measurement of central tendency or

location is the median, obtained by arranging the results in numerical order and identifying the middle one if  $n$  is odd, and the average of the two middle values if  $n$  is even. The median has the advantage that it is unaffected by extreme values and avoids consideration of possible outliers (see below). The standard deviation of the population,  $\sigma$ , is given by

$$\sigma = \left\{ \frac{\sum_{i=1}^n (x_i - \mu)^2}{n} \right\}^{0.5} \quad [4]$$

In practice, since  $\mu$  is estimated using  $\bar{x}$  it is necessary to estimate  $\sigma$  using the sample standard deviation,  $s$ :

$$s = \left\{ \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1} \right\}^{0.5} \quad [5]$$

Equation [5] includes the term  $(n - 1)$  in its denominator rather than  $n$  to ensure that  $s$  is an unbiased estimator of  $\sigma$ . The number  $(n - 1)$  is known as the number of degrees of freedom of the  $s$  value, i.e., the number of independent deviations  $(x_i - \bar{x})$  used to calculate  $s$ . If  $(n - 1)$  such deviations are known, the last deviation can be deduced from the obvious result  $\sum_i (x_i - \bar{x}) = 0$ . The concept of degrees of freedom is much used in significance testing (see below).

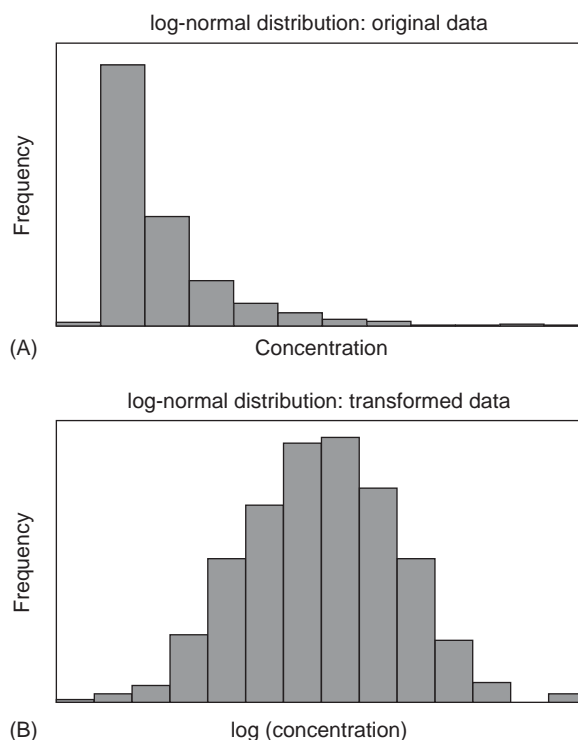

The square of the standard deviation is called the variance (and has many important properties and uses), while the standard deviation expressed as a percentage of the mean, i.e.,  $100s/\bar{x}$ , is called the relative standard deviation (r.s.d.) or the coefficient of variation (c.v.).

## Other Frequency Distributions

The normal distribution is very important in experimental science but other frequency distributions do occur in practice. One important situation quite common in analytical data arises when an otherwise normal distribution has heavy tails, i.e., has more values than expected that are much higher or lower than the mean. This situation may arise when a normal random distribution of errors is supplemented by additional gross errors, i.e., possible outliers (see below). Another cause of heavy-tailed distributions is the superimposition of two or more normal distributions with the same mean but different standard deviations, for example, when the same analysis is done by two or more different people or instruments and the results are combined. Distributions of this kind are now commonly studied using robust statistical methods, which seek to down-weight measurements that are much higher or lower than the mean. (This is regarded as a more logical approach than the use of statistics such as the median (see above), which ignores extreme results completely.) A simple robust

statistic is the 10% trimmed mean, i.e., the mean value calculated after the highest and lowest 10% of the measured values are neglected. This statistic has the advantage that possible outliers are ignored. If there are no such outliers, then the mean obtained is closely similar to the overall mean, so no harm is done. Considering the 100 measurements in Figure 2, their overall mean is 0.4995, and the 10% trimmed mean (i.e., the mean of the 80 values obtained when the highest 10 and the lowest 10 are omitted) has the very similar value 0.5038. Robust standard deviations can also be calculated, and virtually all conventional univariate and multivariate statistical methods can be similarly modified ('robustified') to handle situations where outliers may occur. Robust statistics are considered in detail elsewhere in this encyclopedia.

If a series of measurements, using the same technique in every case, is carried out on a number of different sample materials, another frequency distribution that often occurs is the log-normal distribution. This situation often arises in the natural world (e.g., the concentrations of antibody in the blood sera of different individuals) and in environmental science (e.g., the levels of nitrate in different water samples taken over successive days or weeks). The log-normal distribution curve has a long tail at its high end (Figure 3A), but can be converted to look like a

**Figure 3** The log-normal distribution with the horizontal axis showing (A) measured values and (B) logarithms of the measured values.

normal distribution by plotting the logarithms of the measured values on the horizontal axis (Figure 3B). After transformation in this way, the logarithmic data have the properties expected of a normal distribution. If the mean of the logarithmic values is calculated and its antilogarithm found, it equals the geometric mean of the original values, given by

$$\bar{x}_g = \sqrt[n]{x_1 x_2, \dots, x_n} \quad [6]$$

where  $x_1$ ,  $x_2$ , etc., are the individual measurements. Confidence limits (see below) can be calculated for log-normal data in the same way as for normally distributed results, but again they are the confidence limits of the geometric mean.

Sometimes it is required to test whether a set of measurements could have come from a population with a particular distribution (most commonly the normal distribution). A method for carrying out such tests is described in a later section.

### The Sampling Distribution of the Mean and the Central Limit Theorem

When samples of size  $n$  are repeatedly taken from a population of data, and the sample means –  $\bar{x}$  values – are plotted as a frequency diagram, the result is called the sampling distribution of the mean. A very important statistical principle called the central limit theorem shows that the shape of the curve obtained in such cases will be close to that for a normal distribution, even if the parent population is not normally distributed. This approximation improves as the sample size  $n$  increases. The standard deviation of the  $\bar{x}$  values, generally (and perhaps misleadingly) called the standard error of the mean (s.e.m.), is given by  $\sigma/\sqrt{n}$ . (Inevitably it is necessary in practice to use the estimated value,  $s/\sqrt{n}$ ). This result is (roughly) exemplified by the two numbers in the bottom left-hand corner of Figure 2. The standard deviation of the original 100 measurements is 0.0286, quite close to the simulated value of 0.03. But the standard deviation of the means (s.e.m.) of 25 samples with  $n=4$ , i.e., the 25 column means, is only 0.0167.

Figure 4 summarizes a simulation of the central limit theorem using Microsoft Excel® which gives 250 values of the weight of a vial from a uniform distribution, i.e., all the weights in the range covered (99.6–100.5 mg) should be equally likely to occur. This is approximately true, all the 10 bars in the darker histogram representing the original 250 values having sizes between 20 and 29 results. The paler bars show the effect of taking 50 samples of size five from the same 250 measurements and plotting the mean values of these samples. These bars have a

Figure 4 Microsoft Excel® simulation of the central limit theorem. For details see text.

shape similar to that of the normal distribution, and cover a narrower range than the original data. The importance of the Central Limit Theorem lies in the fact that it allows us to use the properties of the normal distribution to calculate confidence intervals and limits from the relatively small numbers of measurements (small sample sizes) often obtained in analytical work.

### Confidence Limits and Intervals

When a small number of replicate analyses are performed their mean value,  $\bar{x}$  is used to estimate the population mean,  $\mu$ . In the absence of systematic errors (i.e., with unbiased measurements),  $\bar{x}$  would be the true value of the analyte concentration. But because random errors occur  $\bar{x}$  will not be exactly equal to  $\mu$ . We thus wish to define an interval within which  $\mu$  lies with a given degree of probability, and thanks to the central limit theorem we can apply normal distribution properties to the sampling distribution of the mean to do this. Remembering that the standard error of  $\bar{x}$  is  $\sigma/\sqrt{n}$  (see above), the normal distribution shows that 95% of the values of  $\bar{x}$  will lie within  $1.96\sigma/\sqrt{n}$  of the mean. That is, the 95% confidence limits of the mean are given by

$$\mu - 1.96\sigma/\sqrt{n} < \bar{x} < \mu + 1.96\sigma/\sqrt{n} \quad [7]$$

which can be rewritten as

$$\bar{x} - 1.96\sigma/\sqrt{n} < \mu < \bar{x} + 1.96\sigma/\sqrt{n} \quad [8]$$

Equation [8] is more appropriate than [7], as we usually have a single experimental mean  $\bar{x}$  and wish to use it to provide a range for  $\mu$ , the true value. The range  $\mu = \bar{x} \pm 1.96\sigma/\sqrt{n}$  is known as the confidence interval for  $\mu$ . Similarly, 99.7% confidence interval and limits are obtained from  $\mu = \bar{x} \pm 3\sigma/\sqrt{n}$ .

When dealing with small samples, however, it is necessary to adjust the methods just described in two

ways. First, as already noted, we must in practice use  $s$  to estimate  $\sigma$ . A second problem is that as  $n$  diminishes,  $s$  becomes increasingly less reliable as an estimator of  $\sigma$ . This is exemplified in Figure 2. The 25 individual columns of data, i.e., 25 samples with  $n=4$ , have  $s$  values as low as 0.0126 and as high as 0.0458, yet each of these might be taken as an estimate of  $\sigma$ . This problem was famously studied almost a century ago by W.S. Gosset, writing under the pseudonym 'Student'. He showed that confidence intervals derived for small samples are given by

$$\mu = x \pm t_{n-1}s/\sqrt{n} \quad [9]$$

In [9],  $s$  has replaced  $\sigma$  as expected, and the numbers 1.96 or 3,  $z$ -values derived from the properties of the normal distribution, are replaced by the statistic  $t$ . This varies with the sample size  $n$ , becoming larger as  $n$  decreases to take account of the greater unreliability of  $s$  as an estimator of  $\sigma$ . The value of  $t$ , readily obtained from statistical tables using the data for  $(n-1)$  degrees of freedom, also depends on the confidence level required (95%, 99.7%, etc.).

## Uncertainty and the Propagation of Errors

The discussion in the previous section assumed that systematic errors were absent from an analytical experiment. In reality, this assumption can never be justified, and experience (e.g., in the conduct of proficiency testing schemes and method comparison studies) shows that quite large systematic errors can occur in many analyses. In recent years, considerable pressure has developed for all analytical results to be accompanied by an estimate of their uncertainty. The uncertainty of a result provides a range within which the true value of the analyte level is predicted to lie, taking into account all sources of error, and with a given degree of probability, typically 95%. There are two possible approaches to estimating uncertainty. The top-down approach utilizes the results of proficiency testing schemes, in which carefully prepared sample materials are circulated to a number of participating laboratories, each of which estimates the analyte content using its own conventional method. The range of results obtained by different laboratories (evaluated and published independently by a controlling body) then provides, it is argued, an estimate of the overall uncertainty of an analysis for that particular analyte. This approach may underestimate sampling errors (as the samples are specially prepared before dispatch to the participants): equally

it may overestimate the spread of results obtained by a single laboratory. Its main advantage is that it avoids the tedious study of errors occurring in the numerous individual steps in a particular analysis.

If appropriate proficiency scheme results are not available this detailed examination of each step in the analytical process, the so-called bottom-up approach to uncertainty estimates, must be used. In doing so, it is necessary to use a number of equations that allow the calculation of the overall random error arising in a process containing two or more steps. This is technically referred to as the propagation of errors. The basic problem in such cases is that, if the two or more experimental steps have random error sources that are independent of each other, such errors will partly, but not wholly, cancel each other out. In the following equations the final result of the analysis is called  $X$ , and the individual analytical steps contributing to  $X$  are  $A$ ,  $B$ , etc. The random errors in  $X$ ,  $A$ ,  $B$ , etc. (normally standard deviations) are given the symbols  $\delta X$  (which we wish to determine),  $\delta A$ ,  $\delta B$ , etc. Then,

$$\begin{aligned} \text{If } X &= A \pm B \pm C \dots, \\ \text{then } \delta X^2 &= \delta A^2 + \delta B^2 + \delta C^2 + \dots \end{aligned} \quad [10]$$

$$\begin{aligned} \text{If } X &= A/B \text{ or } A \times B \dots, \\ \text{then } (\delta X/X)^2 &= (\delta A/A)^2 + (\delta B/B)^2 + \dots \end{aligned} \quad [11]$$

$$\text{If } X = A^q, \text{ then } (\delta X/X) = q(\delta A/A) \quad [12]$$

Using equations of types [10]–[12] singly or jointly we can combine two or more random error contributions to provide an overall random error estimate. (Note that the independence of the sources of error is assumed throughout. For example, if  $X = A^2$ , then  $(\delta X/X) = 2(\delta A/A)$  from [12]: using eqn [11], giving  $(\delta X/X) = \sqrt{2}(\delta A/A)$ , would be incorrect.) To determine uncertainties we must also include estimates of systematic errors in mathematical forms (i.e., hypothetical population distributions) that allow them to be combined algebraically with the random ones. Guidelines for doing this are provided in the Further Reading section. Although the bottom-up method is potentially tedious, as even the simplest analytical procedures are found on close inspection to involve numerous error-prone steps, it can be very valuable. It reveals the individual steps that contribute most to the overall error, and which thus need to be improved if the range of values given by the uncertainty estimate is to be reduced. Equally, it will reveal steps that contribute little to the overall error, and which are thus not worth trying to improve.

## Significance Testing Principles

The commonest applications of univariate statistics in the analytical sciences are probably in significance testing. We may wish, for example, to decide whether one of the results in a sample of measurements is a possible outlier; to decide whether a data sample could have come from a normal (or some other) population; or to compare two or more means or standard deviations. Although the methods used in these cases differ in detail, the same underlying principles are used in every case. The starting point for such a test is always a null hypothesis ( $H_0$ ), i.e., a hypothesis assuming no difference between the data being compared. So in the examples cited above the null hypotheses would be that the suspect value was not an outlier; that the data *do* fit a normal or other specified distribution; or that the means or standard deviations being compared *do not* differ significantly from one another. The next step is to calculate the probability of obtaining the actual experimental results, assuming the null hypothesis to be correct. If this probability is less than a user-determined value, often  $p = 0.05$  or 5%, sometimes  $p = 0.01$  (1%), etc., then it is concluded that the null hypothesis should after all be rejected. If the probability of getting the experimental data exceeds, e.g., 5%, then the null hypothesis is retained. (The results of such tests should always be expressed in exactly this ' $H_0$  rejected' or ' $H_0$  retained' form, along with a record of the probability level used and the sample size.)

The probability of obtaining the experimental data was until recently determined by converting them into a suitable test statistic (see below) and comparing the result with critical values for that statistic ( $t$ ,  $F$ , etc.). These values are available in standard sets of tables for different numbers of degrees of freedom and different probability levels. Nowadays, it is commoner to use software that provides the probabilities directly, a simpler procedure that moreover gives more detailed information.

There is inevitably a chance that any significance test may lead to an erroneous conclusion. If it is decided to reject a null hypothesis at the  $p = 0.05$  level, there must be a 5% chance that it will be rejected when it should be retained. Such an error is called a type I error. Similarly, it is possible to retain a null hypothesis that should be rejected – a type II error. It is natural to consider that a good test procedure should reject an erroneous null hypothesis as often as possible, so  $(1 - \text{the probability of a type II error})$  is called the power of a test. (For a given test in specified conditions the power is a calculable number, not merely a vague concept.) It is clearly possible to reduce the chance of a type I error occurring by

performing a test at, e.g., the  $p = 0.01$  level rather than at the  $p = 0.05$  level. Unfortunately, for any given sample size this inevitably increases the chance of a type II error occurring. The only way to reduce the chance of both types of error in a given test is to increase  $n$ , i.e., to take more measurements.

Significance tests can be performed as one-tailed (sometimes called one-sided) or two-tailed (two-sided) tests. If two (or more) sets of results are compared with no *a priori* reason to believe that, e.g., one of the mean values should be higher or lower than the other, then the comparison is a two-tailed one: we test to see whether the two results differ or not. This is the commoner situation. In some cases, however, we are only interested in one possibility. For example, in testing the efficacy of a catalyst we only wish to study whether one reaction rate is specifically higher than another: this would require a one-tailed test. The decision on which of the two types of test is required should be taken in advance, but the procedure is very similar whether a one-tailed or two-tailed test is used. The only difference arises in the critical values taken from the statistical tables for the given test, or in the choice made from a software menu.

## Common Significance Tests

Hundreds of significance tests are available for different purposes in the handling of experimental data. Here we outline only those most commonly used in analytical work. One extremely common requirement is to test whether a set of data might come from a normally distributed (or other defined) population. For relatively small samples, the most efficient method is the Kolmogorov test (later adapted by Smirnov, and sometimes known as the Kolmogorov–Smirnov test). The procedure involves comparing the cumulative frequency plot of the data to be tested (this will look like a series of steps, each step corresponding to one measurement) with that of the hypothesized distribution (a smooth curve, often available in graphical form in sets of statistical tables). The maximum vertical distance between the two plots is the test statistic, which can be compared with critical values as usual. In testing for the normal distribution it is necessary to start by transforming the data to the standard normal variable,  $z$ , using eqn [2].

A very common problem in analytical work is the occurrence of outliers, or suspect results, i.e., one (or more) results in a series of replicate measurements that appears to be out of line with the rest. Should the suspect value be rejected before calculation of the mean, standard deviation, etc.? The treatment of

outliers is controversial, as samples drawn from, e.g., a normal distribution may legitimately include some measurements very different from the mean (Figure 1). Robust methods (see above) provide one approach to the problem, but the use of significance tests for outliers is still common. ISO now recommends the Grubbs test for this purpose. The test statistic here,  $G$ , is given by

$$G = |\text{suspect value} - x|/s \quad [13]$$

with  $s$  calculated with the suspect value included. Values of  $G$  above the critical value suggest that the suspect value could be rejected. Like most outlier tests, this method has the twin disadvantages that it is hard to apply when two or more outliers occur, and that it assumes that the population distribution is normal. This could be dangerous: a measurement that appears to be an outlier with the assumption of a normal distribution may not be an outlier if the distribution is, e.g., log-normal.

The important  $F$ -test allows us to compare two standard deviations,  $s_1$  and  $s_2$ , of samples with sizes  $n_1$  and  $n_2$ . We calculate

$$F = s_1^2/s_2^2 \quad \text{or} \quad s_2^2/s_1^2 \quad [14]$$

so that  $F > 1$ . Since the squares of the standard deviations are the variances of the samples, this is sometimes known as the ratio of variances test. Critical values of  $F$  depend on the number of degrees of freedom of each sample,  $(n_1 - 1)$  and  $(n_2 - 1)$ , and on the probability level chosen ( $p = 0.05$ , etc.). Experimental  $F$ -values greater than the critical value allow the rejection of the null hypothesis that the standard deviations are not significantly different. When  $n_1$  and  $n_2$  are small, the critical values of  $F$  are large, i.e., the two standard deviations must be very different before such a divergence becomes statistically significant. If the two standard deviations are found not to be significantly different, they can for some purposes be *pooled* to give a single value of  $s$ , using the equation

$$s^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2} \quad [15]$$

This equation indirectly demonstrates the important additivity properties of variances. The numerator contains the two variances, each multiplied by the respective number of degrees of freedom, and the denominator gives the total number of degrees of freedom for the two samples. So the pooled variance,  $s^2$ , is the average of the two individual variances, taking degrees of freedom into account.

A series of important significance tests is provided by the  $t$ -statistic (see above). Its simplest use is in the comparison of an experimental mean,  $x$  with a true or standard value,  $\mu$ , for example, in testing for systematic errors. In this case the test statistic is given by

$$t = |x - \mu|/\sqrt{n}/s \quad [16]$$

The numerical value of  $t$  is then compared with the critical values at the chosen probability level and  $(n - 1)$  degrees of freedom. Experimental  $t$  values that exceed the critical value lead to a rejection of the null hypothesis that  $\mu$  and  $x$  are not significantly different.

A similar method can be used to compare two mean values,  $x_1$  and  $x_2$  from samples with sizes  $n_1$  and  $n_2$ , respectively. The null hypothesis that these two means are not significantly different is equivalent to the statement that  $(x_1 - x_2)$  is not significantly different from zero. So eqn [16] can be adapted to give

$$t = \frac{|x_1 - x_2|}{s\sqrt{(1/n_1) + (1/n_2)}} \quad [17]$$

where  $s$  is the pooled standard deviation calculated from eqn [15]. The value of  $t$  is again compared with critical values at the desired probability level, and with  $(n_1 + n_2 - 2)$  degrees of freedom. The null hypothesis of equal means can be rejected if the experimental  $t$ -value exceeds the critical one. In the (unlikely) event that the two standard deviations cannot be pooled modified equations are necessary to calculate both  $t$  and the appropriate number of degrees of freedom. These equations are given below.

A final and useful application of the  $t$ -statistic is in the paired  $t$ -test. This is applicable when, e.g., several different materials containing different levels of analyte are studied using two different methods. Any differences between the results of the two methods might be masked by differences between the analyte levels in the samples if a conventional  $t$ -test were used. So it is necessary to determine for each material the difference between the results of the two methods, which would average zero if the null hypothesis, i.e., that the methods give indistinguishable results, is correct. The value of  $t$  is then obtained from

$$t = d\sqrt{n}/s_d \quad [18]$$

where  $d$  and  $s_d$  are the mean and standard deviation, respectively, of the differences between the pairs of results. Again the null hypothesis is rejected if the experimental value of  $t$  exceeds the critical value at the chosen probability level. The number of degrees

of freedom in this case is  $(n - 1)$  where  $n$  is the number of pairs of data.

Comparisons between means (and standard deviations) can be extended to the study of three or more sets of data. Such comparisons require the very important statistical method called analysis of variance (ANOVA).

## Application of Statistical Techniques

Many of the significance tests and other procedures summarized in this article (and many others) are very readily performed with the aid of Microsoft Excel<sup>®</sup>, Minitab<sup>®</sup>, and other widely available programs. Such software also gives instant access to the most important descriptive statistics (mean, median, standard deviation, s.e.m., confidence limits, etc.). In practice, the major problems are therefore (1) accurate entry of the experimental data into the program (this problem may not arise if an analytical instrument is directly interfaced to a PC); and (2) choice of the appropriate test once data entry has been successfully completed. Guidance on the latter

crucial issue is provided by the resources listed in the Further Reading section.

## Introduction

Experimental design methods allow the experimenter to understand better and evaluate the factors that influence a particular system by means of statistical approaches. Such approaches combine theoretical knowledge of experimental designs and a working knowledge of the particular factors to be studied. Although the choice of an experimental design ultimately depends on the objectives of the experiment and the number of factors to be investigated, initial experimental planning (as shown in Figure 1) is essential.

The relationship between the various factors and response within a given system can be shown

mathematically as follows:

$$y = f(x_1, x_2, x_3, \dots, x_k) \quad [1]$$

where  $y$  is the response of interest in the system and  $x$  are the factors that affect the response when their values change. In general, the following types of factors can be distinguished: (1) continuous, e.g., temperature; and (2) discrete, e.g., experimenters. Factors are considered to be independent if there is no relationship between them and dependent if a relationship exists. The values or settings attributed for each factor are called levels. Each experimental run in an experimental design study requires that one or more treatments (stimulus applied to one or more factors) be applied to the system and the response measured. The experimenter then employs statistical design methods to determine if the treatment of interest or combination of treatments was significant in influencing the response of the system under study. Calculation of the treatment effects can then be used to identify which variables lead to an optimal response.

of freedom in this case is  $(n - 1)$  where  $n$  is the number of pairs of data.

Comparisons between means (and standard deviations) can be extended to the study of three or more sets of data. Such comparisons require the very important statistical method called analysis of variance (ANOVA).

## Introduction

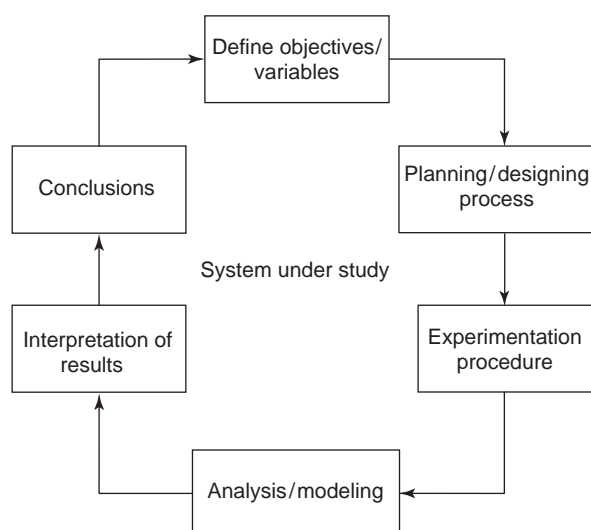

Experimental design methods allow the experimenter to understand better and evaluate the factors that influence a particular system by means of statistical approaches. Such approaches combine theoretical knowledge of experimental designs and a working knowledge of the particular factors to be studied. Although the choice of an experimental design ultimately depends on the objectives of the experiment and the number of factors to be investigated, initial experimental planning (as shown in Figure 1) is essential.

The relationship between the various factors and response within a given system can be shown

mathematically as follows:

$$y = f(x_1, x_2, x_3, \dots, x_k) \quad [1]$$

where  $y$  is the response of interest in the system and  $x$  are the factors that affect the response when their values change. In general, the following types of factors can be distinguished: (1) continuous, e.g., temperature; and (2) discrete, e.g., experimenters. Factors are considered to be independent if there is no relationship between them and dependent if a relationship exists. The values or settings attributed for each factor are called levels. Each experimental run in an experimental design study requires that one or more treatments (stimulus applied to one or more factors) be applied to the system and the response measured. The experimenter then employs statistical design methods to determine if the treatment of interest or combination of treatments was significant in influencing the response of the system under study. Calculation of the treatment effects can then be used to identify which variables lead to an optimal response.

**Figure 1** Essential criteria during early experimental planning.

The two main applications of experimental design are screening, in which the factors that influence the experiment are identified, and optimization, in which the optimal settings or conditions for an experiment are found. A screening experiment is a systematic approach to identifying the key input parameters of a process or product that affect the output performance. The usual approach is to start with a screening design including all controllable factors that may possibly influence the experiment, identify the most important ones, and then proceed with an experimental optimization design.

## Experimental Designs

### Full Factorial Designs (Two Levels per Factor)

The most general two-level design is a full factorial design and described as  $2^k$ -designs where the base 2 stands for the number of factor levels and  $k$  the number of factors each with a high and low value. In a full factorial design, the levels of the factors are chosen in such a way that they span the complete factor space. Often, only a lower and upper level is chosen. With two factors, this defines a square in the factor space, and with three factors, this defines a cube. The lower level is usually indicated with a '−' sign; the higher level with a '+' sign.

The method can be graphically illustrated in a simplified example: the effects of reaction temperature and pH in determining the spectrophotometric response (absorbance) of a standard analyte solution. **Figure 2** shows a graphical definition of the experimental domain, with the reaction temperature varying from 40°C (low level) to 60°C (high level)

**Figure 2** Graphical definition of the effects of reaction temperature and pH in determining the spectrophotometric response of a standard analyte solution.

**Table 1** Experimental matrix: spectrophotometric response of a standard analyte solution

Experiment number	Temperature	pH	Response
A	− 1	− 1	$y_1$
B	+ 1	− 1	$y_2$
C	− 1	+ 1	$y_3$
D	+ 1	+ 1	$y_4$
Factor levels			
(−)	40°C	pH 1	
(+)	60°C	pH 3	

and the reaction pH varying from 1 (low level) to 3 (high level). The best experimental points in the domain are located in the corners A, B, C, and D as follows: A (40°C, pH 1); B (60°C, pH 1); C (40°C, pH 3); D (60°C, pH 3).

The four trials of experimental matrix used in this experiment are shown in **Table 1**, with the results of each experiment indicated in the response column and the factor levels in the rows below the experimental matrix. Note that −1 is used for the low level of each factor and +1 for the high level.

If we introduce another variable (e.g., reagent concentration) in the experiment, it is then possible to represent the factors as faces on one or more cubes with the responses at the points. The distribution of experimental points within this type of experimental domain ( $2^3$  design) is shown schematically in **Figure 3**.

### Fractional Factorial Design

Fractional factorial designs are arguably the most widely used designs in experimental investigations,

**Figure 3** Full factorial design at two levels,  $2^3$  design.

and mainly used for the screening portion of experiments. Such designs are good alternatives to a full factorial design, especially in the initial stage of a project, and considered a carefully prescribed and representative subset of a full factorial design. In fractional factorial designs, the number of experiments is reduced by a number  $p$  according to a  $2^{k-p}$  design. In the most commonly employed fractional design, the half-fraction design ( $p=1$ ), exactly one-half of the experiments of a full design are performed.

Suppose a situation occurs in which three factors, each at two levels are of interest, but the experimenter does not want to run all eight treatment combinations ( $2^3 = 8$ ). A design with four treatment combinations can then be performed when considering the one-half fraction of the  $2^3$  design ( $2^{3-1} = 4$ ).

The fractional factorial design is based on an algebraic method of calculating the contributions of factors to the total variance with less than a full factorial number of experiments. Such designs are useful when the numbers of potential factors are relatively large because they reduce the total number of runs required for the overall experiment. However, by reducing the number of runs, a fractional factorial design will not be able to evaluate the impact of some of the factors independently.

### Latin Squares

A Latin square is a block design with the arrangement of  $v$  Latin letters into a  $v \times v$  array (a table with  $v$  rows and  $v$  columns). Latin square designs are often used in experiments where subjects are allocated treatments over a given time period where time is

thought to have a major effect on the experimental response. Suppose the treatments are labeled A, B, and C. In this particular situation, the design would be

Day 1	A B C
Day 2	C A B
Day 3	B C A

This type of design allows the separation of an additional factor from an equal number of blocks and treatments. If there are more than three blocks and treatments, then a number of Latin square designs are possible. It can be noted that Latin square designs are equivalent to specific fractional factorial designs (e.g., the  $4 \times 4$  Latin square design is equivalent to a  $4^{3-1}$  fractional factorial design).

### Greco-Latin Squares

The Greco-Latin square design involves two Latin squares that are superimposed on each other. It contains two treatment factors instead of one and contains four factors overall instead of three. An example design would look as follows:

	A <sub>1</sub>	A <sub>2</sub>	A <sub>3</sub>	A <sub>4</sub>
B <sub>1</sub>	C <sub>1</sub> D <sub>3</sub>	C <sub>2</sub> D <sub>4</sub>	C <sub>3</sub> D <sub>1</sub>	C <sub>4</sub> D <sub>2</sub>
B <sub>2</sub>	C <sub>4</sub> D <sub>2</sub>	C <sub>1</sub> D <sub>1</sub>	C <sub>2</sub> D <sub>3</sub>	C <sub>3</sub> D <sub>4</sub>
B <sub>3</sub>	C <sub>3</sub> D <sub>1</sub>	C <sub>4</sub> D <sub>2</sub>	C <sub>1</sub> D <sub>3</sub>	C <sub>2</sub> D <sub>4</sub>
B <sub>4</sub>	C <sub>2</sub> D <sub>4</sub>	C <sub>1</sub> D <sub>3</sub>	C <sub>3</sub> D <sub>2</sub>	C <sub>4</sub> D <sub>1</sub>

The analysis for the Greco-Latin square design is similar to that of a Latin square design. However, one noticeable difference is that two treatment sum of squares have to be computed (factors C and D) by listing two sets of means outside the design table. As an additional note, Greco-Latin squares are most effective if replicated and are subject to the same randomization rules as for the Latin squares.

### Response Surface Designs (More than Two Levels for One or More Factors)

Response surface methodology is designed to allow experimenters to estimate interactions, therefore giving them an idea of the shape of the response surface they are investigating. This approach is often used when simple linear and interaction models are not adequate, e.g., experimentation far from the region of optimum conditions. Here, the experimenter can expect curvature to be more prevalent and will need a mathematical model, which can represent the curvature. The simplest such model has the quadratic

form:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_{12} X_1 X_2 + \beta_{11} X_1^2 + \beta_{22} X_2^2 \quad [2]$$

which contains linear terms for all factors, squared terms for all factors, and products of all pairs of factors. The two most common designs generally used in response surface modeling are central composite designs and Box–Behnken designs. In these designs the inputs take on three or five distinct levels, but not all combinations of these values appear in the design.

Central composite designs contain imbedded factorial or fractional factorial design with center points that is augmented with a group of axial (star) points that allow estimation of curvature (Figure 4). One central composite design consists of cube points at the corners of a unit cube that is the product of the intervals  $[-1, 1]$ , star points along the axes at or outside the cube, and center points at the origin. Points A, B, C, and D are the points of the initial factorial design with points E, F, G, and H being the star points at the central 0.

A central composite design always contains twice as many star points as there are factors in the design. The star points represent new extreme values (low and high) for each factor in the design. There are three types of central composite designs, ultimately depending on where the star points are placed. Circumscribed central composite designs are the original forms of the central composite design. The star points are at some distance  $\alpha$  from the center based on the properties desired for the design and the number of factors in the design. The  $\alpha$  values depend on the number of factors in the factorial part of the design.

Inscribed central composite designs are a scaled down version of the circumscribed version in that they use the factor settings as the star points and create factorial or fractional factorial design within those limits. In other words, inscribed designs are those where each factor of the circumscribed version is divided by  $\alpha$  for their generation. Face centered central composite designs occur when the star points are at the center of each face of the factorial space, where  $\alpha = \pm 1$ .

### Box–Behnken Designs

The Box–Behnken is considered an efficient option in response surface methodology and an ideal alternative to central composite designs. It has three levels per factor, but avoids the corners of the space, and fills in the combinations of center and extreme levels (Figure 5). It combines a fractional factorial with incomplete block designs in such a way as to avoid the

**Figure 4** Central composite design consisting of a full factorial two-level and star design.

**Figure 5** Box–Behnken design with three levels per factor.

extreme vertices and to present an approximately rotatable design with only three levels per factor. A design is rotatable if the variance of the predicted response at any point  $x$  depends only on the distance of  $x$  from the design center point. It must be noted, however, that Box–Behnken designs should be confined to uses where the experimenter is not interested in predicting response at extremes (corners of the cube).

### Mixture Designs

In a mixture design experiment, the independent factors are proportions of different components of a

blend and often measured by their portions, which sum to 100% or normalized to 1, i.e.,

$$\sum_{i=1}^N X_i = 1 \quad \text{for } x_i \geq 0 \quad [3]$$

As shown, mixture components are subject to the constraint that they must equal to the sum of one. In this case, standard mixture designs for fitting standard models such as simplex-lattice and simplex-centroid designs are employed. When mixtures are subject to additional constraints, constrained mixture designs (extreme-vertices) are then appropriate. Like the factorial experiments discussed above, mixture experimental errors are independent and identically distributed with zero mean and common variance. In addition, the true response surface is considered continuous over the region being studied. Overall, the measured response is assumed to depend only on the relative proportions of the components in the mixture and not on the amount.

## Glossary

- Blocking** procedure by which experimental units are grouped into homogeneous clusters in an attempt to improve the comparison of treatments by randomly allocating the treatments within each cluster or 'block'.
- Control** A control is a treatment, which is included to provide a reference set of data which can be compared with data obtained from the experimental treatments.
- Experiment** An investigation in which the investigator applies some treatment(s) to experimental units to be observed and evaluated by measuring one or more response variables.
- Experimental unit** A physical entity or subject subjected to the treatment independently of other units.
- Factor** A categorical explanatory variable studied in an experiment, e.g., pH, flow rate.
- Factorial designs** A factorial design is used to evaluate two or more factors simultaneously. The treatments are combinations of levels of the factors. The advantages of factorial designs over one-factor-at-a-time experiments are that they are more efficient and allow interactions to be detected.
- Levels** The different values assigned to a factor.
- Randomization** A random assignment of experimental material to treatments prior to the start of the experiment. Randomization is vital in the experimental design process and provides: (1) the basis for a valid interpretation of the experimental outcomes in terms of a test of statistical significance, and (2) the basis for computing a valid estimate of experimental error by justifying the assumption of independence of responses over experimental units.
- Replication** When a given combination of factors is present in a system, replication can be used to: (1) demonstrate that results are reproducible, (2) provide a degree of assurance against erroneous results due to unforeseen reasons, (3) provide the means to estimate experimental error, and (4) provide the capacity to increase

	the precision for proper estimates of treatment means.		to address the objectives of a particular experiment.
Response variable	A characteristic of an experimental unit measured after treatment and analyzed	Treatments	The set of circumstances created for an experiment.

## Optimization Strategies

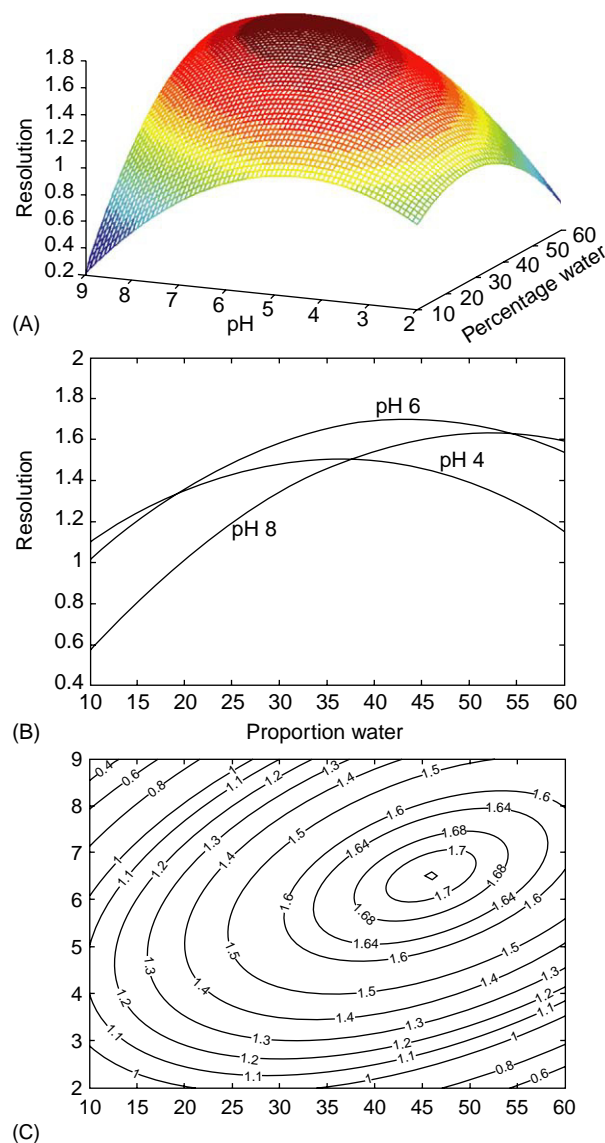

R G Brereton, University of Bristol, Bristol, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Optimization has a significant role in analytical science. There are many reasons for finding an optimum. For example, it may be important to maximize the extraction efficiency of a compound from a matrix; there may be a large number of factors involved in the extraction procedure. Other examples involve improving chromatographic separations and optimizing the factors that influence signal intensity in atomic spectroscopy.

Traditional methods involve studying the influence of one factor at a time. For example, we might want to look at chromatographic resolution of two compounds using isocratic conditions, as a function of proportion of water (using a mobile phase of water and acetonitrile) and acidity (as controlled by the nature and amount of buffer). We do not know how the resolution varies as a function of proportion of water and pH prior to the experiment. **Figure 1A** illustrates a possible underlying response surface. We might try to set pH at a constant level, then vary the percentage water, until we reach an optimum, then set this percentage constant, varying the pH until a fresh optimum is chosen, which we use as the best conditions. The problem with this strategy is illustrated in **Figure 1B**. The change in resolution as a function of proportion of water differs according to pH, so a different optimum proportion of water is found according to the pH that is used. Hence, if we performed an optimization in which the initial experiments were performed at pH 4, we would obtain a different result for the best conditions to an optimization at pH 8 and so, in both cases a false optimum unless we happen by accident to have hit on the correct pH in the original experiments. The reason for this is that the influence of pH and mobile phase composition are said to interact and so cannot be considered independent factors. If there are several different factors involved in an optimization

## Optimization Strategies

### Introduction

Optimization has a significant role in analytical science. There are many reasons for finding an optimum. For example, it may be important to maximize the extraction efficiency of a compound from a matrix; there may be a large number of factors involved in the extraction procedure. Other examples involve improving chromatographic separations and optimizing the factors that influence signal intensity in atomic spectroscopy.

Traditional methods involve studying the influence of one factor at a time. For example, we might want to look at chromatographic resolution of two compounds using isocratic conditions, as a function of proportion of water (using a mobile phase of water and acetonitrile) and acidity (as controlled by the nature and amount of buffer). We do not know how the resolution varies as a function of proportion of water and pH prior to the experiment. **Figure 1A** illustrates a possible underlying response surface. We might try to set pH at a constant level, then vary the percentage water, until we reach an optimum, then set this percentage constant, varying the pH until a fresh optimum is chosen, which we use as the best conditions. The problem with this strategy is illustrated in **Figure 1B**. The change in resolution as a function of proportion of water differs according to pH, so a different optimum proportion of water is found according to the pH that is used. Hence, if we performed an optimization in which the initial experiments were performed at pH 4, we would obtain a different result for the best conditions to an optimization at pH 8 and so, in both cases a false optimum unless we happen by accident to have hit on the correct pH in the original experiments. The reason for this is that the influence of pH and mobile phase composition are said to interact and so cannot be considered independent factors. If there are several different factors involved in an optimization

**Figure 1** (A) Response surface for a typical chromatographic resolution as pH and proportion of water (in a water–acetonitrile mixture) is altered. (B) Resolution as a function of proportion of water at three different values of pH. (C) Representation as a contour plot.

it can be extremely hard to find true optima using traditional methods.

In order to overcome these difficulties, it is necessary to employ systematic approaches for determination

of the optimum. The simplest method for overcoming the problem could be a grid design. This would involve performing the experiment at a range of different pHs and proportion of water (e.g., 10 in each case), there would be 100 possible combinations. In every case, the separation is performed and the resolution measured. This would prevent the experimenter from missing key information that could happen by accident using traditional approaches. Once it appears that an optimum has been found, another series of experiments could be performed around the best points in the grid, using a finer step-size, should it be desired to obtain an even more accurate optimum. Although this method is likely to yield an appropriate result, there are several weaknesses. The major one is that a large number of experiments need to be performed. This wastes time and if there are several factors involved is impracticable. A second one is that experiments are often irreproducible, and if the optimum is flat, it can often be hard to find an exact position. The third is that it ignores observations that could easily be made during the process of the optimization. **Figure 1C** is the contour representation of the response. It is clear that the optimum will not be found in the top left, so performing a large number of experiments in that region is a waste of time. The experimenter only needs to perform a few to notice that this is far from the optimum.

Therefore, it is possible to refine the simple grid search to help find an optimum more quickly. There are statistical rules that allow optimization to be performed rapidly and safely, which can be used formally by the analytical scientist. This article describes some of the main approaches.

## Screening

The first step in many designs involves screening. Often there may be a large number of possible factors that influence a response. For example, we may be interested in determining the extraction efficiency of a process. There may be many different factors, such as oven temperature, pH, extraction time, nature of the filter, enzymes, or reagents added (where appropriate), and so on. The first step an experimenter should do is to list these factors. Some will be irrelevant and so it is not worth spending time on studying their influence, whereas others may have a significant effect. The first step in many optimizations is to eliminate those factors that are not interesting, and this is called screening. In order to do this it is normal to perform a series of experiments at different levels of the factors.

## Full Factorial Designs

The principles of how these designs are set up are described in more detail elsewhere in this encyclopedia.

Although it is not difficult to perform a screening experiment for two factors, in realistic cases it is more likely that there will be many more factors; for example, if we want to screen for six factors,  $2^6$  or 64 experiments are required. The extra experiments are mainly used to study what are called the interaction terms. For example, a two-factor full factorial design at two levels requires  $2^2$  or four experiments. These experiments can be used to obtain a model between the response and the level of the factors often expressed in the form

$$y = b_0 + b_1x_1 + b_2x_2 + b_{12}x_1x_2$$

where  $y$  is the response, the  $x$ s represent the coded values of the factors and the  $b$ s are the coefficients. The term  $b_{12}$  is called an 'interaction' term; if four experiments are performed, four terms are studied, one of which is an interaction factor. For a six-factor, 64 experiment, design, most of the experiments are used to study interaction terms including five- or six-term interactions between the factors. Whereas these terms may be interesting, especially the lower order interactions, for the purpose of screening we are primarily interested in the significance of the single-factor terms, and it is only necessary to perform  $f+1$  experiments for an  $f$  factor design (the extra experiment being used to determine the intercept or average), or seven experiments in the case of six factors. Hence,  $64 - 7$  or 57 of the original experiments are unnecessary for the purpose of screening, wasting time. If the number of factors is small (e.g., three), it is still worth doing a full factorial design, but when the number of factors becomes large it is prohibitive to perform a full factorial, and tricks are required to reduce the number of experiments.

## Fractional Factorial Designs

Consider a three-factor, two-level design. Eight experiments are listed in **Table 1**, the conditions being coded as usual. How can we reduce the number of experiments safely and systematically? Two-level fractional factorial designs are used to reduce the number of experiments by 1/2, 1/4, 1/8, and so on. Can we halve the number of experiments? At first glance, a simple approach might be to take the first four experiments of **Table 1**. However, these would leave the level of the first factor at  $+1$  throughout. A problem is that we now no longer study the variation of this factor, so we do not obtain any information on how factor 1 influences the response.

Can a subset of four experiments be selected that allows us to study all three factors? Rules have been developed to produce these fractional factorial designs obtained by taking the correct subset of the original experiments. **Table 2** illustrates a possible fractional factorial design that enables all factors to be studied.

The matrix of effects can be calculated as presented in **Table 2** and is also interesting. A full model for three factors is given by

$$y = b_0 + b_1x_1 + b_2x_2 + b_{12}x_1x_2 + b_{13}x_1x_3 + b_{23}x_2x_3 + b_{123}x_1x_2x_3$$

Note that there are eight terms, corresponding to eight experiments. The last four terms are not interesting at this stage, but the values of  $x$  can be calculated, simply by multiplying the relevant columns. Whereas the first four columns of this matrix are all different, the last four each correspond to one of the first four columns. For example the  $x_1x_2$  column exactly equals the  $x_3$  column. What does this imply? As the number of experiments is reduced, the amount of information is correspondingly reduced. Since only four experiments are now performed, it is only possible to measure four unique factors. The interaction between factors 1 and 2 is said to be 'confounded' with factor 3. This might mean, for example, that, using this design the interaction between factors 1 and 2 is indistinguishable from the influence of factor 3 alone. However, not all interactions will be

significant, and the purpose of a preliminary experiment is often simply to sort out which main factors should be studied in detail later.

Note that two-level fractional factorial designs only exist when the number of experiments equals a power of 2. In order to determine the minimum number of experiments, the following procedure is adopted:

1. Determine how many terms are interesting.
2. Then construct a design whose size is the next greatest power of 2.

### Plackett–Burman Designs

Where the number of factors is quite large, the constraint that the number of experiments must equal a power of 2 can be rather restrictive. Since the number of experiments must always exceed the number of factors by at least one, this would mean that 32 experiments are required for the study of 19 factors, and 64 experiments for the study of 43 factors. In order to overcome this problem and reduce the number of experiments further, other approaches are needed.

Plackett and Burman proposed a number of two-level factorial designs, where the number of experiments is a multiple of 4 as opposed to a power of 2. Hence, designs exist for 4, 8, 12, 16, 20, 24, etc., experiments. The number of experiments exceeds the number of factors,  $f$ , by 1.

One such design is given in **Table 3** for 11 factors and 12 experiments and has various features:

1. In the first row, all factors are at the same level.
2. The first column from rows 2 to  $f$  is called a 'generator'. The key to the design is that there are only certain allowed generators that can be obtained from tables. Note that the number of factors will always be an odd number equal to  $f = 4m - 1$  (or 11 in this case), where  $m$  is any integer. If the first row consists of '–', the generator will consist of  $2m$  ( $= 6$  in this case) experiments at the '+' level and  $2m - 1$  ( $= 5$  in this case) at the '–' level, the reverse being

**Table 1** Three-factor full factorial design with a '+' indicating a high level and a '–' indicating a low level of each factor

10	–	–	–	+	+	+	–	+	+	–	+
11	+	–	–	–	+	+	+	–	+	+	–
12	–	+	–	–	–	+	+	+	–	+	+

true if the first row is at the ‘+’ level. In Table 3, the generator is + + – + + + + – – – + –. 3. The next  $4m - 2$  ( $= 10$  in this case) columns are generated from the first column simply by shifting the down cells by one row. This is indicated by diagonal arrows in the table. Notice that experiment 1 is not included in this procedure.

4. The level of factor  $j$  in experiment (or row) 2 equals to the level of this factor in the row  $f$  for factor  $j - 1$ . For example, the level of factor 2 in experiment 2 equals the level of factor 1 in experiment 12.

There are as many high as low levels of each factor over the 12 experiments, as would be expected. The most important property of the design, however, is called ‘orthogonality’. Consider the relationship between factors 1 and 2. There are six instances in which factor 1 is at a high level, and six at a low level. For each of the six instances at which factor 1 is at a high level, in three cases factor 2 is at a high level, and in the other three cases it is at a low level. A similar relationship exists where factor 1 is at a low level. This implies that the factors are orthogonal or uncorrelated, an important condition for a good design. Any combination of two factors is related in a similar way. Only certain generators possess all these properties, so it is important to use only known generators for the designs.

Standard Plackett–Burman designs exist for 7, 11, 15, 19, and 23 factors; generators are given in Table 4. Note that for 7 and 15 factors it is also possible to use conventional fractional factorial designs, and it can be shown that the two approaches are equivalent, except that the columns and rows are swapped around; so, in such situations, it makes no difference as to which approach is adopted.

**Table 4** Generators for Plackett–Burman designs

Factors	Generator
7	+ + + – + – –
11	+ + – + + + – – – + –
15	+ + + + – + – + + – – + – – –
19	+ + – + + + + – + – + – – – – + +
	–
23	+ + + + + – + – + + – – + + – – +
	– + – – – –

If the number of experimental factors is less than that of a standard design (a multiple of  $4 - 1$ ), the final factors are ‘dummy’ ones. Hence, if there are only 10 real factors, use an 11 factor design, the final factor being a dummy one: this may be a variable that has no effect on the experiment, such as the technician who handed out the glassware, or the color of laboratory furniture.

## Designs for Optimization Requiring Modeling

For a typical analytical chemical problem, preliminary considerations, if necessary using screening designs, will reduce the number of factors to a manageable amount, typically between two and five. The next phase is to study these in detail, including their interactions. The most common approaches require a series of experiments, the results of which are then analyzed using a mathematical model, which results in an equation that expresses the response as a function of the coded values of the factors. The optimum of the response surfaces (e.g., the best resolution or highest extraction efficiency) can be determined in one of three ways. The first is by using a computational optimization package, often available as part of commercial package for the analysis data obtained from experimental designs. The second is by visualizing a response surface and determining the optimum graphically; this is feasible mainly if the number of factors is limited. The third is algebraically, using calculus, solving differential equations.

Note that although a model may already have been obtained using a screening design, such a model is rarely useful for optimization studies, because usually only linear terms are estimated. Most screening designs do not involve recording replicates, which is important in order to know how well the model is obeyed, nor do they provide information on squared terms, for example, the dependence of the response on  $x^2$ , which are important for optimization; some such as Plackett–Burman and highly fractional factorials do not even provide details of interactions.

Two of the most common classes of design are described below, although there are many other potential methods used throughout analytical chemistry.

### Central Composite or Response Surface Designs

Many designs for optimization are based on the central composite design (sometimes called a response surface design). Table 5 illustrates a typical design used to optimize a procedure with three factors, temperature, pH, and time.

A major advantage of response surface designs is that in addition to linear and interaction terms they can include squared terms, because the factors are at several levels. For many situations in optimization, these terms are important to provide curvature in the resultant response surface. Hence, after using screening designs that mainly indicate which factors are important, it is possible to then study in detail how the factors influence the optimum, and once a model is obtained to predict the experimental optimum conditions.

### Mixture Designs

A separate set of designs are important in analytical chemistry, where the factors add up to a constant total, an example being the composition of a mobile

phase in chromatography. Special designs called mixture designs are used in such situations.

Most chemists represent their experimental conditions in mixture space, which corresponds to all possible allowed proportions of components that add up to 100%. A three component mixture can be represented by a triangle (Figure 2), which is a two-dimensional cross-section of a three-dimensional space showing the allowed region in which the proportions of the three components add up to 100%. Points within this triangle or mixture space represent possible mixtures or blends. As the number of components increases so does the dimensionality of the mixture space. Physically meaningful mixtures can be represented as points in this space, for two components the mixture space is simply a straight line, for three components a triangle, for four components a tetrahedron.

There are a number of common designs that can be envisaged as ways of determining a sensible number and arrangement of points within the simplex.

The most widespread are the simplex centroid designs. For  $f$  factors they involve performing  $2^k - 1$  experiments, i.e., for four factors, 15 experiments are performed. It involves all possible combinations of the proportions 1, 1/2, to 1/ $f$ . A three-factor design consists of three single-factor combinations, three

binary combinations, and one ternary combination, as presented in **Table 6**.

Another class of designs called ‘simplex lattice’ designs have been developed and are often preferable to the reduced simplex centroid design when it is required to reduce the number of interactions. They span the mixture space more evenly. A  $\{f, m\}$  simplex lattice design consists of all possible combinations of  $0, 1/m, 2/m, \dots, m/m$ , or a total of  $N = (f + m - 1)! / [(f - 1)!m!]$  experiments where there are  $k$  factors. A  $\{3, 3\}$  simplex lattice design can be set up analogous to the  $\{3, 3\}$  simplex centroid design given in **Table 7**.

Special designs are required when there are constraints on the factors. This is quite common in analytical chemistry. For example, if we want to study chromatographic separations using a three-solvent mixture, it is often not useful to study the separations using pure solvents. There are several types of constrained mixture designs, which may be represented graphically by a region of the original mixture space. For three components a constrained mixture design is illustrated in **Figure 3**.

Once the design is performed, it is normal to fit a mathematical model to the response (e.g., signal intensity, resolution, extraction efficiency) according

**Figure 3** Constrained mixture design.

to the values of the factors, and this allows the optimal conditions to be calculated. If there are two or three factors, this can be visualized as in **Figure 4**.

**Figure 4** Visualizing an optimum in a three-factor mixture space.

## Sequential Methods for Optimization

The best known sequential method for optimization is the simplex method. This requires the experimenter to perform a series of experiments until he or she reaches an optimum. The response surface is not mathematically modeled, but the experimenter follows a series of rules until he or she cannot improve. A simplex is the simplest possible object in  $N$  dimensional space, e.g., a line in one dimension, and a triangle in two dimensions. Simplex optimization means that a series of experiments are performed on the corners of such a figure.

The most common, and easiest to understand, method of simplex optimization is called the fixed sized simplex.

The main steps are as follows, exemplified by a two-factor experiment:

1. Define how many factors of interest, which we will call  $k$ .
2. Perform  $k + 1$  ( $= 3$  for two factors) experiments on the vertices of a simplex (or triangle for two factors) in factor space. The conditions for these experiments depend on the step-size. This defines the final 'resolution' of the optimum. The smaller the step-size the better the optimum can be defined, but more experiments are necessary. It is important to establish sensible initial conditions, especially the spacing between the experiments.
3. Rank the response (e.g., the chromatographic resolution) from 1 (worst) to  $k + 1$  (best). In vector form the conditions for the  $n$ th response are given by  $\mathbf{x}_n$  where each element in the vector corresponds to the value of a factor, e.g., pH or eluotropic strength in a chromatographic separation.
4. Establish new conditions for the next experiment as follows:

$$\mathbf{x}_{\text{new}} = \mathbf{c} + \mathbf{c} - \mathbf{x}_1$$

**Figure 5** Progress of a typical fixed size simplex.

where  $\mathbf{c}$  is the centroid of the responses 2 to  $k + 1$  (excluding the worst response), defined by the average of these responses represented in vector form.

5. Continue as in steps 3 and 4 unless the new conditions result in a response that is worst than the remaining  $k$  ( $= 2$ ) conditions, i.e.,  $y_{\text{new}} < y_2$  where  $y$  is the corresponding response and the aim is maximization. In this case return to the previous conditions, and calculate

$$\mathbf{x}_{\text{new}} = \mathbf{c} + \mathbf{c} - \mathbf{x}_2$$

where  $\mathbf{c}$  is the centroid of the responses 1 and 3 to  $k + 1$  (excluding the second worst response) and can also be expressed by  $\mathbf{x}_{\text{new}} = \mathbf{x}_1 + \mathbf{x}_3 - \mathbf{x}_2$ , for two factors. Keep these new conditions together with the worst and the  $k - 1$  best responses from the previous simplex. The second worst response from the previous simplex is rejected.

6. Check for convergence. When the simplex is at an optimum it normally oscillates around in a triangle or hexagon. If the same conditions reappear, stop. There are a variety of stopping rules, but it should generally be obvious when optimization has been achieved.

The progress of a fixed sized simplex is illustrated in **Figure 5**. Many elaborations have been developed over the years. One of the most important is the  $k + 1$  rule. If a vertex has remained part of the simplex for  $k + 1$  steps, perform the experiment again. The reason for this is that response surfaces may be noisy, so

an unduly optimistic response could have been obtained because of experimental error. This is especially important when the response surface is flat near the optimum. Another important problem relates to boundary conditions. Sometimes there are physical reasons why a condition cannot cross a boundary, an obvious case being a negative concentration. It is not always easy to deal with such situations, but it is possible to use step 5 rather than step 4 above under such circumstances. If the simplex constantly tries to cross a boundary either the constraints are a little unrealistic and so should be changed, or the behavior near the boundary needs further investigation. Starting a new simplex near the boundary with a small step-size may solve the problem.

A weakness with the standard method for simplex optimization is a dependence on the initial step-size. Another method is called the modified simplex algorithm and allows the step size to be altered, reduced as the optimum is reached, or increased far from the optimum.

For the modified simplex, step 4 of the fixed sized simplex is changed as follows. A new response at point  $\mathbf{x}_{\text{test}}$  is determined, where the conditions are obtained as for fixed sized simplex:

1. If the response is better than all the other responses in the previous simplex, i.e.,  $y_{\text{test}} > y_{k+1}$  then 'expand' the simplex, so that

$$\mathbf{x}_{\text{new}} = \mathbf{c} + \alpha(\mathbf{c} - \mathbf{x}_1)$$

where  $\alpha$  is a number greater than 1, typically equal to 2.

2. If the response is better than the worst of the other responses in the previous simplex, but worse than the second worst, i.e.,  $y_1 < y_{\text{test}} < y_2$ , then 'contract' the simplex but in the direction of this new response

$$\mathbf{x}_{\text{new}} = \mathbf{c} + \beta(\mathbf{c} - \mathbf{x}_1)$$

where  $\beta$  is a number less than 1, typically equal to 0.5.

3. If the response is worst of the other responses, i.e.,  $y_{\text{test}} < y_1$ , then 'contract' the simplex but in the opposite direction of this new response

$$\mathbf{x}_{\text{new}} = \mathbf{c} - \beta(\mathbf{c} - \mathbf{x}_1)$$

where  $\beta$  is a number less than 1, typically equal to 0.5.

4. In all other cases simply calculate

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{test}} = \mathbf{c} + \mathbf{c} - \mathbf{x}_1$$

as in the normal (fixed-sized) simplex.

Then perform another experiment at  $\mathbf{x}_{\text{new}}$  and keep this new experiment plus the  $k$  ( $=2$ ) best experiments from the previous simplex to give a new simplex. Rule 5 of the fixed sized simplex still applies, if the value of the response at the new vertex is less than that of the remaining  $k$  responses, return to the original simplex and reject the second best response, repeating the calculation as above.

There are yet further sophistications such as the supermodified simplex, which allows mathematical modeling of the shape of the response surface to provide guidelines as to the choice of the next simplex. Simplex optimization is only one of several computational approaches to optimization, including evolutionary optimization, and steepest ascent methods, however, it is the most commonly used sequential method in analytical chemistry, with diverse applications ranging from autosimming of instruments to chromatographic optimizations, and can easily be automated.

## Multivariate Classification Techniques

M J Adams, RMIT University, Melbourne, VIC, Australia

### Introduction

As instrumental chemical analysis techniques have become more sophisticated with increasing levels of automation, the number of samples routinely analyzed has grown and the amount of data per sample has increased and can appear overwhelming.

Multivariate classification techniques attempt to make sense of these data by identifying inherent patterns that may provide insight into the structure and form of the data and, hence, of the samples themselves. This general area of study is referred to as pattern recognition; a field rich in applications in analytical science. For example, the identification of the origin of goods and foodstuffs is an important task for the analyst. Given a limited set of possibilities then the problem at hand is one of classification. From a training set of samples of known origin a classification scheme is developed that can classify unknown, test samples. In the biochemical field, nuclear magnetic resonance (NMR) spectroscopy of biofluids and cells provides a unique insight into changes in metabolism caused by drugs and toxins. Although biological NMR spectra are extremely complex the essential diagnostic parameters are carried in the overall patterns of the spectra. Metabonomics employs pattern recognition methods to interrogate the databases of proton NMR spectra. This approach allows a mathematical classification of toxicity based on disparate types of multidimensional metabolic data so giving new insights into the modes and biochemical mechanisms of toxicity. This work is of value in the prediction of toxicity in drug development studies.

The aims of pattern recognition are to determine summarizing structure within analytical data, using, for example, exploratory data analysis techniques and cluster analysis, and to identify such patterns (classification) according to their correspondence with previously characterized examples. Many numerical techniques are available to the analytical scientist wishing to interrogate their data, but all have the same starting point. The data are expressed in a matrix form in which each sample, or object, is described by a vector of measurements. This representation leads logically to the concept of a pattern space with as many dimensions as the number of

**Figure 1** Three objects, A, B, and C, displayed in the three-dimensional pattern space defined by the variables  $x_1$ ,  $x_2$ , and  $x_3$ . Objects A and B are closer to each other, and therefore considered more similar, than to object C.

variables in the vector, and an object occupying a single point in that multidimensional space. Furthermore, it is assumed that points representing similar patterns (i.e., similar samples) will tend to cluster in the pattern space. Conversely, samples of dissimilar patterns will lie in different regions of space (Figure 1).

### Data Reduction

It is often the case, particularly in spectrochemical analysis, that the number of variables far exceeds the number of samples. This is not surprising given that a single infrared spectrum, for example, can comprise absorption measurements at several thousand wavelengths. Although there are many statistical techniques available for identifying the major variables (features) responsible for defining the pattern space occupied by a sample, by far the most common technique employed in chemometric analysis of analytical data is the method of principal components analysis (PCA). The method is an important tool for analysts in exploratory data analysis.

PCA involves rotating and transforming the original axes representing the original variables into new axes, so that the new axes lie along the directions of maximum variance of the data. These new axes are orthogonal, i.e., the new variables are uncorrelated. Because of the high correlation that frequently exists between analytically measured

variables, it is generally found that the number of new variables needed to describe most of the sample data variance is significantly less than the number of original variables. Thus, PCA provides a means to reduce the dimensionality of the parameter space. In addition, PCA can reveal those variables, or combinations of variables, that describe some inherent structure in the data and these may be interpreted in chemical or physicochemical terms.

Principal components are linear combinations of original variables, and the linear combination with the largest variance is the first principal component (Figure 2). Once this is determined, then the search proceeds to find a second normalized linear combination that has most of the remaining variance and is uncorrelated with the first principal component. The procedure is continued, usually until all the principal components have been calculated and a subset of the

principal components is then selected for further analysis and for interpretation. The scheme for performing PCA is illustrated in Figure 3.

PCA can often be so effective and efficient in reducing the dimensionality of analytical data that it can provide immediate visual indication of patterns within data and is a commonly employed exploratory technique.

## Unsupervised Pattern Recognition

In many initial, exploratory studies information concerning the presence of groups of similar samples, or the pattern design of such groups as may be present, is not known. This may be due to a lack of knowledge of the pattern generating process. Indeed, this could be the principal aim of the study – to determine the inherent designs of patterns existing within the analytical data. The purpose of unsupervised pattern recognition is to identify groups, or clusters, of similar objects characterized by a multivariate feature set. No *a priori* information about the structure of possible groups present is required.

The general aim is to attempt to partition a given dataset into homogeneous subsets (clusters) according to similarities of the points in each subset and their relationship to the elements of other subsets. This approach is referred to as cluster analysis. Quantification of the degree of similarity of objects expressed in pattern space is a key process in cluster analysis.

It is generally accepted without proof that similarity and distance are complementary; objects close together in multidimensional space are more alike than those further apart. Most of the similarity measures used in practice are based on some distance function, and whilst many such functions are referenced in the literature the most common is the simple Euclidean distance metric.

In multidimensional space the Euclidean distance,  $d_{(1,2)}$ , between two objects is given by

$$d_{(1,2)} = \sqrt{\sum_{j=1}^m (X_{1,j} - X_{2,j})^2} \quad [1]$$

**Figure 2** The first principal component, PC1, is a new axis representing the combination of original variables providing the greatest variance in the data.

**Figure 3** The original data,  $X$ , comprising  $n$  objects or samples described by  $m$  variables, is converted to a dispersion (covariance or correlation) matrix  $C$ . The eigenvalues,  $\lambda$ , and eigenvectors,  $L$ , are extracted from  $C$ . A reduced set of eigenvectors,  $L^{\text{red}}$ , i.e., selected and the original data projected into this new, lower-dimensional pattern space  $Y$ .

**Figure 4** In multidimensional pattern space the Euclidean distance,  $d_{(A,B)}$ , between two objects A and B is provided by the square root of the sum of the squares of the differences between the values of the defining variables,  $\Delta x_j$ .

where  $x_1$  and  $x_2$  are the feature vectors of objects 1 and 2 and  $m$  is the number of variables (Figure 4). The Euclidean distance can be calculated for all pairs of objects and the data matrix transformed into a square, symmetric distance matrix.

There are basically two approaches to data clustering, dynamic methods and hierarchical techniques.

### Dynamic Clustering

Dynamic clustering employs an iterative algorithm to optimize some clustering criterion function such as the average affinity of points to a cluster's mean value – the  $c$ -means algorithm. During each iteration, a data point is assigned to a cluster on the basis of its closeness to the cluster's center. The cluster centers are recalculated to reflect changes brought about by data point assignments, and the new cluster models are used in the next iteration to reclassify the data. The process is continued until a stable partition is obtained, i.e., until no object is reclassified. The number of expected clusters or groups must be specified before commencing the analysis.

With the  $c$ -means algorithm a mean vector is taken as representing a cluster and for asymmetric shaped clusters this will be inadequate. The algorithm can readily be generalized to more sophisticated models so that a cluster is represented not by a single point (such as described by a mean vector) but rather by a function describing some attribute of the cluster's shape in pattern space.

### Hierarchical Cluster Analysis

Hierarchical cluster analysis is noniterative and various implementation methods are commonly encountered in analytical science. Initially, each object in the dataset is considered as a separate cluster. At each subsequent stage of the algorithm the two clusters that are most similar are merged to create a new cluster. The algorithm terminates when all clusters are combined. The number of clusters in the dataset does not need to be known or provided *a priori*. Using the original data matrix, a suitable matrix of similarity measures between objects is first constructed (e.g., the Euclidean distance matrix). From this similarity matrix, the most similar objects are combined to produce a new 'grouped' object and the process repeated until all objects have been included in a single cluster. The choice of an appropriate similarity metric and the manner in which objects are grouped (or clustered) gives rise to many combinations of potential methods. Popular interpoint distances used for clustering are the nearest neighbor, furthest neighbor, and the mean (Figure 5).

The choice of measure may greatly influence the result of clustering. The nearest neighbor metric will link together quite distinct clusters if there exists a path of closely located points connecting the two clusters. The furthest neighbor algorithm does not suffer this problem but can be very sensitive to outliers and will not detect elongated clusters. The hierarchical structure of clusters provided by the algorithm is represented graphically by a dendrogram (Figure 6).

The dendrogram illustrates the cluster merging sequence and the corresponding values of the similarity measure employed. A threshold similarity value, selected by the user, splits the data into the perceived correct number of clusters. Generally, the threshold level should be chosen so that intercluster distances are considerably greater than the intracluster distances.

The application of unsupervised pattern recognition methods should be undertaken with caution. Many factors will influence the results of the analysis, including variable scaling, metric used, similarity measure, clustering criterion, number of data points, etc. Dynamic clustering methods can be computationally efficient, particularly with large data sets, but unrealistic groupings can easily be achieved and analysis with several different cluster representative functions is recommended. If the number of samples is small then describing some cluster representation function is meaningless and in such situations hierarchical methods are more useful.

Cluster analysis is not a statistical based operation and should not be employed to prove the existence of groups. Rather, cluster analysis is best employed as

**Figure 5** The distance between object A and the existing cluster can be defined by its proximity to the cluster's nearest neighbor,  $d_{NN}$ , its center,  $d_M$ , or its furthest neighbor,  $d_{FN}$ .

**Figure 6** A dendrogram provides a two-dimensional representation of the similarity between objects according to the distance between an object and a cluster. A threshold level, selected by the user, defines the number of distinct groups in the data.

part of the toolkit for exploratory data analysis. The evidence for certain groups and clusters, and the cause of structure found should be investigated by other techniques.

## Supervised Pattern Recognition

Whereas cluster analysis neither needs nor assumes *a priori* information about cluster properties or pattern design, supervised pattern recognition uses a training

set of known group members to define patterns and develop partition functions. The aim is to identify and quantify relationships between groups, and assign unclassified objects to one of the groups.

A wide range of modeling algorithms is available to perform this type of classification. Widely used techniques include the  $k$ -nearest neighbor ( $k$ -NN) method and linear discriminant analysis (LDA).

### Nearest Neighbor Classification

For successful operation the nearest neighbor rules for classification rely on knowing a large number of correctly, previously classified patterns. The basic principles are that samples that are close together in pattern space are likely to belong to the same class or have similar distributions of the classes. The first idea gives rise to formulation of the single nearest neighbor rule, 1-NN, and the second provides for extension of the rule to  $k$ -NNs.

A test object to be classified is assigned to that class containing its nearest neighbor as measured by some distance metric. The Euclidean distance is easily calculated and is often used. This 1-NN scheme can readily be extended to more ( $k$ ) neighbors with the class assignment decided according to a majority vote procedure, i.e., assignment to the class most represented in the set of  $k$ -NN classified objects. Common values for  $k$  are 3 or 5 (Figure 7).

The sample-based decision boundary between groups is defined by the relatively small number of samples belonging to the outer envelopes of the clusters. Those samples deeply imbedded within clusters do not contribute to defining the boundary and may be discarded for classification of new objects. This concept can be exploited for increasing the computational efficiency of nearest neighbor classification since the distance from a new, unclassified object to every classified sample need not be calculated. A variety of so-called condensing algorithms is available and aims to provide a subset of the complete training dataset such that 1-NN classification of any new pattern with the subset is identical to 1-NN classification with the complete set.

Since nearest neighbor methods are based on similarity measured by some distance metric then variable scaling and the units used to characterize the data can influence results. Variables with the largest amount of scatter (greatest variance) will contribute most strongly to the Euclidean distance and in practice it may be advisable to standardize variables before performing classification analysis.

### Discriminant Function Analysis

In LDA, or discriminant function analysis, we are seeking to create new synthetic features (variables)

**Figure 7** With nearest neighbor classification a cluster is defined by the elements in the boundary layer and an object is classified as belonging to that group containing its nearest neighbor. Object A will be assigned to group 1 rather than group 2.

that are linear combinations of the original variables and that best indicate the differences between the known groups in contrast to the variable variances within the groups.

The process of performing LDA aims to derive and construct a boundary between the known classes of the training objects using statistical parameters. This boundary is derived using a discriminant function that provides a value or score when applied to a test object that indicates the group to which the new object should be assigned.

If  $f(x_i, k)$  is some measure of likelihood of object  $x_i$  belonging to group or class  $k$ , then the discriminant score  $D_i$ , for assigning  $x_i$  to one of two classes is given by

$$D_i = f(x_i, k_1) - f(x_i, k_2) \quad [2]$$

which may be interpreted as saying we classify test object  $x_i$  into class 1 if  $D_i$  is positive, otherwise  $x_i$  is considered as belonging to class 2.

The value of the discriminant score is calculated from a linear combination of the recorded values of the variables describing the objects, each suitably weighted to provide optimum discriminatory power. For two variables

$$D_i = w_0 + w_1x_{i,1} + w_2x_{i,2} \quad [3]$$

The weights, or variables coefficients used in calculating  $D$  (eqn [3]), are determined by

$$w = (\bar{x}_j(1) - \bar{x}_j(2))S^{-1} \quad [4]$$

$$w_0 = -\frac{1}{2}[(\bar{x}_j(1) - \bar{x}_j(2))S^{-1}(\bar{x}_j(1) + \bar{x}_j(2))]$$

This represents the ratio of the separation of the means of the two groups to the within-group variance for the groups as given by the pooled covariance matrix,  $S$ .

$\bar{x}_j(1)$  and  $\bar{x}_j(2)$  are the vectors of the mean values for variable  $j$  for groups (1) and (2), respectively, and easily obtained from

$$\bar{x}_j(k) = \frac{\sum_{i=1}^{n(k)} x_{i,j}(k)}{n(k)} \quad [5]$$

where  $n(k)$  is the number of objects in group ( $k$ ), and  $x_{i,j}(k)$  is the value for object  $i$  of variable  $j$  in group ( $k$ ).

The pooled covariance matrix,  $S$ , of two training classes is given by

$$S = \frac{S_{(1)} + S_{(2)}}{n(1) + n(2) - 2} \quad [6]$$

$S_{(k)}$  represents the covariance matrix of group ( $k$ ).

The vector of weights coefficients can be thus be calculated from the classified training data and the discriminant score computed for each new, unclassified sample.

The discriminant function is linear; all the terms are added together to give a single number, the discriminant score.

For higher-dimensional pattern space the boundary is a hyperplane of  $m - 1$  dimensionality, where  $m$  is the number of variables. The partition boundary between two classes is defined at  $D_i = 0$  and in the two-dimensional case it is given by

$$w_0 + w_1x_{i,1} + w_2x_{i,2} = 0 \quad [7]$$

The classification boundary bisects a line between the centroids of the two clusters (Figure 8).

A useful result of performing LDA is the production of what is termed a discriminant plot, where every data point (from the training set or the new test sample set) is projected onto the discriminant function displayed as one-dimensional axis (Figure 9).

The concept of a linear discriminant axis reduces the multidimensional classification problem to a single dimension, with the projection achieved so that discrimination between classes is preserved as well as possible.

## Bayes Classification

The application of discriminant analysis can be extended to include probabilities of class membership and, assuming a multivariate normal distribution of data, confidence intervals for class boundaries can be calculated. The Bayes rule for classification simply states that 'an object should be assigned to that

**Figure 8** Linear discriminant analysis provides a linear partition boundary between the two known groups, bisecting the line between the centroids of the two groups.

**Figure 9** A discriminant plot projects the data on to a single axis (defined by the discriminant function).

group having the highest conditional probability'. If there are two possible classes, then a sample is assigned to group 1 if

$$P_{(1|x)} \geq P_{(2|x)} \quad [8]$$

where  $P_{(1|x)}$  is the conditional probability for group 1 given the pattern vector  $x$ . This conditional probability can be estimated from

$$P_{(1|x)} = \frac{P_{(x|1)} \cdot P_{(1)}}{P_{(x|1)} \cdot P_{(1)} + P_{(x|2)} \cdot P_{(2)}} \quad [9]$$

where  $P_{(1)}$  and  $P_{(2)}$  are the probabilities of the sample belonging to group 1 or group 2 in the absence of analytical data.

$P_{(x|1)}$  express the conditional probability of the pattern  $x$  arising from a member of group 1.

Thus, a sample is assigned to group 1 if

$$P_{(x|1)} \cdot P_{(1)} > P_{(x|2)} \cdot P_{(2)} \quad [10]$$

and the partition boundary where a sample has equal likelihood of belonging to group 1 or group 2, is

**Figure 10** A Coomans plot provides a visual representation of classification results and probability boundaries can also be displayed ( $P_1 = 0.95$  and  $P_2 = 0.95$  levels are illustrated here).

given by

$$P_{(x|1)} \cdot P_{(1)} = P_{(x|2)} \cdot P_{(2)} \quad [11]$$

If the data are assumed to come from a population having a multivariate normal distribution and it is furthermore assumed that the covariance matrix of each group is similar, then the conditional probability values can be calculated from the multidimensional normal distribution

$$P_{(x|k)} = \frac{1}{2\pi|S|^{1/2}} \exp[-0.5(x - \bar{x}_k)^T S^{-1}(x - \bar{x}_k)] \quad [12]$$

where  $S$  is the covariance matrix and  $\bar{x}_k$  the vector of variable means for group  $k$ .

The term  $(x - \bar{x}_k)^T S^{-1}(x - \bar{x}_k)$  is a squared metric (the Mahalanobis distance),  $dm_k^2$ , representing the distance of each object from a group center taking into account correlation within the data.

Using the vectors of means for each group, then values for  $dm_1$  and  $dm_2$  can be calculated for every sample. A plot of  $dm_1$  against  $dm_2$  is referred to as a Coomans plot and displays the results of classification (Figure 10).

On the same diagram probability boundaries (confidence levels) can also be displayed. By substitution into eqn [12], the partition boundary is given by

$$P_{(1)} \exp(-0.5 dm_1^2) = P_{(2)} \exp(-0.5 dm_2^2) \quad [13]$$

and since  $P_{(2)} = 1 - P_{(1)}$ , then this equation can be rearranged to

$$dm_1 = \sqrt{dm_2^2 + 2 \ln\left(\frac{P_{(1)}}{1 - P_{(1)}}\right)} \quad [14]$$

Selecting an appropriate value for  $P_{(1)}$  then  $dm_1$  values can be obtained for a range of  $dm_2$  values, and similarly  $dm_2$  values for a set of given  $dm_1$  figures.

Classification and discriminant analysis algorithms are available with all multivariate statistical software packages. New or modified procedures are regularly being introduced and the application of such techniques and methods in analytical science is growing.

## Multivariate Calibration Techniques

**G Hanrahan, F Udeh, and D G Patil**, California State University, Los Angeles, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Calibration is the process of measuring the instrument response ( $y$ ) of an analytical method to known concentrations of analytes ( $x$ ) using model building and validation procedures. These measurements, along with the predetermined analyte levels, encompass a calibration set. This set is then used to develop a mathematical model that relates the amount of sample to the measurements by the instrument. In some cases, the construction of the model is simple due to relationships such as Beer's Law in the application of ultraviolet spectroscopy.

Traditional univariate calibration techniques involve the use of a single instrumental measurement to determine a single analyte. In an ideal chemical measurement using high-precision instrumentation, an experimenter may obtain selective measurements linearly related to analyte concentration (**Figure 1A**). However, univariate techniques are very sensitive to the presence of outlier points in the data used to fit a

particular model under normal experimental conditions. Often, even only one or two outliers can seriously skew the results of a least squares analysis. The problems of selectivity and interferences (chemical and physical) also limit the effectiveness of univariate calibration methods causing some degree of nonlinearity (**Figure 1B**). In addition, such calibration techniques are not well suited to the multitude of data collected from the sensitive, high-throughput instrumentation currently being used in the analytical sciences. These datasets often contain large amounts of information, but in order to fully extract and correctly interpret this information, analytical methods incorporating a multivariate approach are needed.

In multivariate calibration, experimenters use many measured variables ( $x_1, x_2, \dots, x_k$ ) simultaneously for quantifying the target variable (a variable whose value is to be modeled and predicted by others (i.e., the variable on the left of the equal sign in linear regression)). In order to effectively use multivariate techniques, proper experimental design is essential. Experimental design allows the proper assessment of systematic variability (e.g., interferences) and helps in minimizing, for example, the effects of random noise. Experimental design is often limited by problems associated with the estimation of experimental

Selecting an appropriate value for  $P_{(1)}$  then  $dm_1$  values can be obtained for a range of  $dm_2$  values, and similarly  $dm_2$  values for a set of given  $dm_1$  figures.

Classification and discriminant analysis algorithms are available with all multivariate statistical software packages. New or modified procedures are regularly being introduced and the application of such techniques and methods in analytical science is growing.

## Introduction

Calibration is the process of measuring the instrument response ( $y$ ) of an analytical method to known concentrations of analytes ( $x$ ) using model building and validation procedures. These measurements, along with the predetermined analyte levels, encompass a calibration set. This set is then used to develop a mathematical model that relates the amount of sample to the measurements by the instrument. In some cases, the construction of the model is simple due to relationships such as Beer's Law in the application of ultraviolet spectroscopy.

Traditional univariate calibration techniques involve the use of a single instrumental measurement to determine a single analyte. In an ideal chemical measurement using high-precision instrumentation, an experimenter may obtain selective measurements linearly related to analyte concentration (**Figure 1A**). However, univariate techniques are very sensitive to the presence of outlier points in the data used to fit a

particular model under normal experimental conditions. Often, even only one or two outliers can seriously skew the results of a least squares analysis. The problems of selectivity and interferences (chemical and physical) also limit the effectiveness of univariate calibration methods causing some degree of nonlinearity (**Figure 1B**). In addition, such calibration techniques are not well suited to the multitude of data collected from the sensitive, high-throughput instrumentation currently being used in the analytical sciences. These datasets often contain large amounts of information, but in order to fully extract and correctly interpret this information, analytical methods incorporating a multivariate approach are needed.

In multivariate calibration, experimenters use many measured variables ( $x_1, x_2, \dots, x_k$ ) simultaneously for quantifying the target variable (a variable whose value is to be modeled and predicted by others (i.e., the variable on the left of the equal sign in linear regression)). In order to effectively use multivariate techniques, proper experimental design is essential. Experimental design allows the proper assessment of systematic variability (e.g., interferences) and helps in minimizing, for example, the effects of random noise. Experimental design is often limited by problems associated with the estimation of experimental

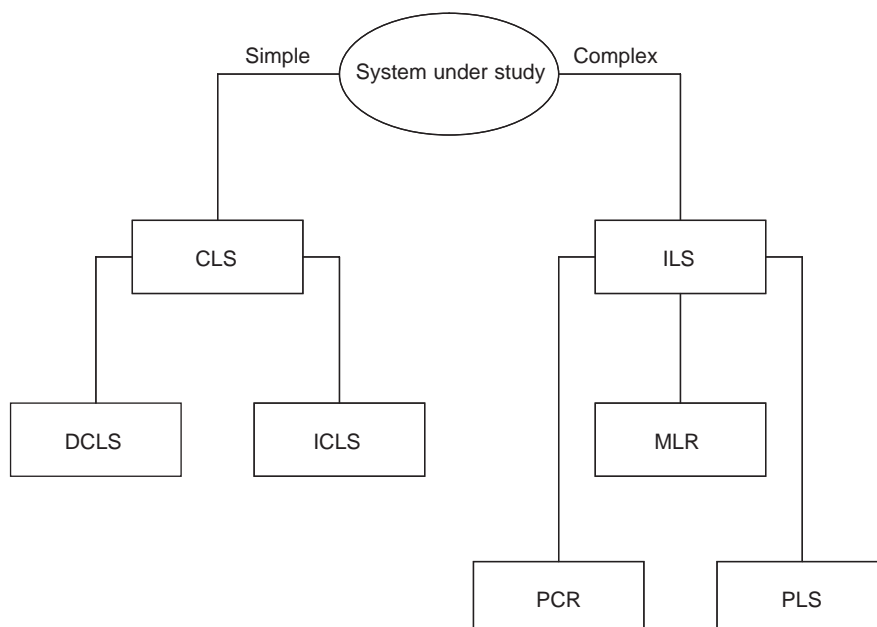

**Figure 1** (A) An ideal chemical measurement where ( $y$ ) is linearly related to ( $x$ ). (B) How selectivity and interference problems limit the effectiveness of univariate calibration methods causing nonlinearity.

parameters, and in some cases the data do not contain sufficient information to obtain proper estimates of the parameters. This can be especially true in latent variable models, where extremely large training sets are often needed to provide enough information for efficient parameter estimation. It is then paramount to search for optimum experimental designs to maximize the information. Forming a decision tree (Figure 2) can be a useful design tool in determining which multivariate calibration technique to use in a given problem.

Both classical least squares (CLS) and inverse least squares (ILS) approaches should be considered. The main advantages and disadvantages of both approaches are listed in Table 1, with detailed descriptions of the various techniques within both approaches described below.

### Data Preprocessing

Data preprocessing is a very important step in many chemometric techniques, which can be used separately (before a method is applied), or as a self-adjusting procedure that forms part of the chemometric methods. Ideally, data preprocessing can be used to remove known interference(s) from data to improve selectivity and enhance more important information to improve robustness. Techniques such as principal components (PCs; see 'Principal components regression' section below) are scale dependent. If one variate has a much higher variance than the others, it is necessary to scale the original variates before

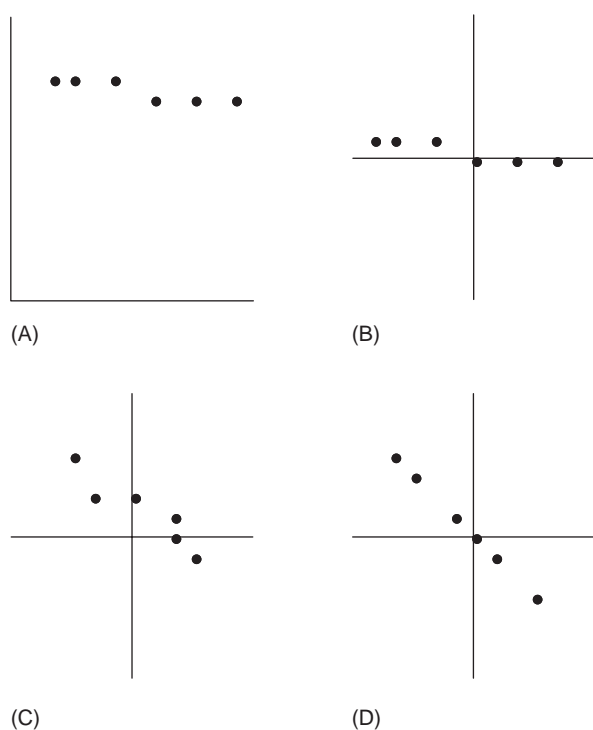

**Figure 2** Multivariate calibration decision tree.

**Table 1** Main advantages and disadvantages of CLS and ILS multivariate calibration approaches

Approach	Advantages	Disadvantages
CLS	Used in estimating multivariate limits of detection, often based directly on Beer's Law Used for moderately complex mixtures  Wavelength selection is not necessarily required for calibration Averaging effects make it less susceptible to noise	Not useful for mixtures with components that interact Requires knowledge of all components in calibration mixture Susceptible to baseline effects
ILS	Used in estimating multivariate limits of detection, often based directly on Beer's law Allows calibration of very complex mixtures  Calculations are relatively fast	Interferences must be included in model Wavelength selection can be difficult and time consuming Accurate calibration often requires large numbers of samples Number of wavelengths used in the model limited by the number of calibration samples

**Figure 3** Scaling technique effects: (A) original data, (B) column centered, (C) autoscaled, and (D) autoscaled profiles.

calculating PCs. Common preprocessing scaling techniques include (but not limited to) column centering, autoscaling, column standardization, and autoscaled profiles (Figure 3). Other data preprocessing techniques used in chemometrics include variance normalization, baseline corrections (first and second derivative, subtraction), and path length corrections (MSC, SNV, thickness).

### Classical Least Squares

The CLS (also known as K-Matrix) approach is best applied to systems where the concentration of every

analyte in the sample is known and obeys a linear relationship with measurement vectors. For a single wavelength and a single analyte, this relationship (Beer's Law) can be explained mathematically by the following equation:

$$A_{\lambda} = \varepsilon_{\lambda} b c \quad [1]$$

where  $A_{\lambda}$  is the absorbance at wavelength  $\lambda$ ,  $\varepsilon_{\lambda}$  the molar absorption coefficient at wavelength  $\lambda$  ( $\text{l mol}^{-1} \text{cm}^{-1}$ ),  $b$  the cell path length (cm), and  $c$  the concentration of the analyte ( $\text{mol l}^{-1}$ ). The absorbances can be normalized to a constant cell path length and results in the simplified relationship:

$$A_{\lambda} = k_{\lambda} c \quad [2]$$

where  $k_{\lambda}$  is the single constant combination of the absorptivity coefficient and path length. This equation can be easily solved by measuring the absorbance of a single sample of known concentration and using these values to solve for  $k_{\lambda}$ . Multivariate systems (e.g., analytes A and B) are more complex and the mixture of analytes is equal to the sum of the instrument responses to the component responses (Figure 4).

The final response of the instrument to this mixture can be represented as

$$A_{\lambda} = K c \quad [3]$$

As shown in the decision tree (Figure 1), two CLS methods are used, direct (DCLS) and indirect (ICLS). In the DCLS method, pure spectra are measured directly. In the ICLS method, pure spectra are estimated using mixtures.

### Inverse Least Squares

In the ILS approach, the dependent variable (concentration) is solved by calculating a solution from multiple independent variables (responses at

**Figure 4** Mixture of analytes in multivariate systems.

the selected wavelengths). This is different from CLS where absorbance at a single wavelength is calculated as an additive function of the component concentrations. In ILS, we can combine the absorptivity coefficient ( $\varepsilon_i$ ) and cell path length ( $b$ ) from Beer's Law to form a single constant relationship (matrix notation) with concentration:

$$c = PA_i \quad [4]$$

where  $P$  is the matrix of coefficients. The ILS approach is used in complex mixtures where it is not necessary to obtain the spectra of pure analytes present. The three inverse techniques of multiple linear regression (MLR), principal components regression (PCR), and partial least squares (PLS) are discussed in detail below.

### Multiple Linear Regression

MLR is a method used to estimate the size and statistical significance of the relationship between a dependent variable ( $y$ ) and one independent or predictor variable, ( $x_1$ ), after adjustment for confounders ( $x_2, \dots$ ). As discussed earlier, models constructed from spectroscopy are relatively simple due to linear combinations of the instrumental measurements. Models for a broader range of conditions (i.e., measurements from several wavelengths) have been constructed in order to separate overlapping peaks elicited from the analyte plus other unknown components or conditions. These multiple linear methods for separating outliers are based upon the following equation:

$$x_i = b_0 + b_1y_{i1} + b_2y_{i2} + \dots + b_qy_{iq} + e_i \quad [5]$$

where  $x_i$  is the analyte level of the  $i$ th specimen;  $y_{ij}$  the  $j$ th instrumental measurement with the  $i$ th

specimen;  $b$  the model parameters, and  $e_i$  the error associated with  $x_i$ . Simply, it finds a set of partial regression coefficients such that  $y$  could be approximated as well as possible by a linear combination of the independent variables. The value of the partial coefficients can be found using ordinary least squares (OLR) and the MLR equation can be expressed conveniently in matrix notation. MLR is useful in situations where the number of variables is small, not significantly collinear, and has a strong relationship to the response of the system. When one or more of these conditions is sacrificed, MLR can be inefficient. When the number of variables is reduced, for example, poorer error detection and less precise estimates can occur.

### Principal Components Regression

PCR is a two-step multivariate calibration method involving compression of the data ( $x$ -) matrix into latent variables by principal components analysis (PCA), followed by MLR. PCA (also known as Karhunen–Loève expansion or Eigen- $xy$  analysis) mathematically transforms a number of possibly correlated variables into a smaller number of uncorrelated variables called eigenvectors (or PCs). Essentially, PCA is the breakdown of the original data matrix ( $X$ ) to a product of scores matrix ( $T$ ) and a loadings matrix ( $L$ ). The loading matrix describes the direction of the PC. These relationships can be represented by the equation:

$$X = TL^T$$

where the superscript  $T$  is the transpose of a matrix. The PCs of PCA decomposition represent the spectral variations that are common to all of the spectroscopic calibration data. Therefore, using that information to calculate a regression equation will produce a robust model for predicting concentrations of the desired constituents in very complex samples. The latent variable which best describes the relative distances between objects is given by the direction of maximum variance. **Figure 5** illustrates a two PC situation for two variables,  $x_1$  and  $x_2$ . The first PC accounts for as much of the variability in the data as possible and termed the first PC (PC1). The second PC (PC2) accounts for as much of the remaining variability as possible and is orthogonal (at right angles) to PC1.

Further PCs can be determined by the continuation of this process. However, most of the variation is often found with the combination of PC1 and PC2, thus resulting in a two-dimensional representation of

**Figure 5** PCA with two variables,  $x_1$  and  $x_2$ .

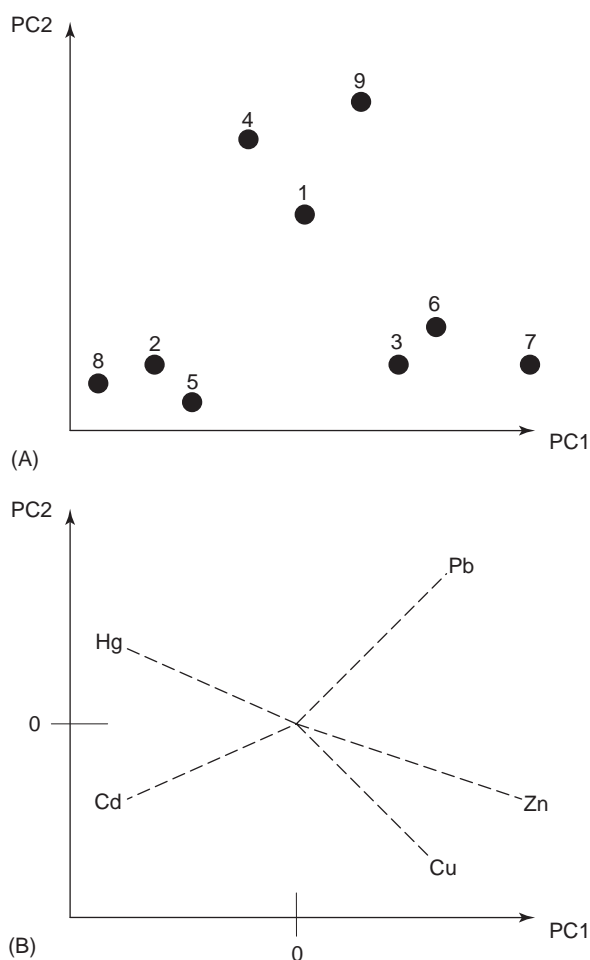

**Table 2** PCA applied to the determination of heavy metals in various sites of a coastal waterway

Site	Cd ( $\mu\text{g l}^{-1}$ )	Hg ( $\mu\text{g l}^{-1}$ )	Zn ( $\mu\text{g l}^{-1}$ )	Cu ( $\mu\text{g l}^{-1}$ )	Pb ( $\mu\text{g l}^{-1}$ )
1	2.5	0.28	42.1	2.9	9.9
2	8.6	0.19	69.8	7.5	12.0
3	3.0	0.26	84.0	4.6	8.9
4	3.9	0.25	64.6	7.9	9.8
5	10.2	0.20	75.8	10.2	11.5
6	4.0	0.19	89.2	13.0	7.6
7	5.3	0.29	99.7	11.9	13.3
8	3.9	0.13	48.9	3.9	8.2
9	4.2	0.18	50.6	5.2	20.3

the data. The main issue in employing PCA for data modeling is that of choosing the appropriate number of retained components. When estimating the number of PCs (latent variables) to use, criteria such as the percentage of explained variance, Scree-test, and cross validation are considered. Overall, PCA works extremely well for the detection of experimental patterns, trends, and groups among multivariate datasets as well as for outlier detection. Let us consider an example of PCA applied to the determination of heavy metals in various locations along a coastal waterway. Table 2 lists the nine sites analyzed and the elements detected.

Figures 6A and 6B show the data analyzed using a simple PCA approach with two PCs (PC1 and PC2). Figure 6A shows the relevant score matrix of the site locations. The score matrix tells the experimenter where the points lie along the new coordinate axis. Figure 6B depicts the loadings and how much the original variables contribute to the principle component.

As mentioned, PCR is a two-step process; the PC scores and the PC loadings are calculated with the PC scores regressed against the analyte concentrations using a regression method. In PCR, the PC scores are chosen to describe as much of the variation in the predictors as possible. The total variance of the experimental dataset and the sum of the eigenvalues

**Figure 6** (A) PCA score matrix of heavy metal determinations from various coastal waterway locations. (B) PCA loadings and how much the original variables contribute to the principle component.

both equal the number of variables. Note that the PCA eigenvectors and scores can be calculated independently of any knowledge of these concentrations and merely represent the largest common variations among all the spectra in the dataset. Most likely, these variations will be related to changes in the analyte concentrations. In applications with collinear  $x$ -variables, PC scores with smaller eigenvalues will likely be more influenced by  $x$ -noise than PC scores with larger eigenvalues. Such conditions exist, for example, in near-infrared analysis where spectral data are highly collinear. The PCR method represents a considerable improvement over MLR and CLS. By using latent variables (scores), it is possible to use a large number of variables (frequencies), but without having knowledge of all possible interferences.

### Partial Least Squares Regression

PLS was originally developed in the 1960s as an ecometric method, but is now employed by many

chemometricians. There are actually two versions of the PLS algorithm (PLS-1 and PLS-2). In an experimental context, PLS can be presented as a kind of simultaneous PCA and regression. The practical implication of this approach is that the experimenter may create new explanatory variables while carrying the same information as the original explanatory variables. Like PCR, PLS is a spectral decomposition technique highly used in multivariate calibration. However, PLS is a one-step process with no regression step involved. Instead, PLS performs the decomposition on both the spectral and concentration data simultaneously.

In an original PCR analysis, for example, only the spectra are taken into account for the determination of the PC scores. For PLS the analyte concentrations of the calibration samples are also incorporated. The factors are presented in such a way that the variation of the content substances can be clarified, as well as possible, by the PCs which are to be determined. Calibration by means of PLS therefore requires, under normal circumstances, fewer factors than a PCR calibration. However, PLS does have its limitations. For example, this approach is often times not appropriate for screening factors that have a minimum effect on the response. Calculations in PLS are generally slower than most classical methods, especially PLS-1. PLS-2 calibrates for all constituents simultaneously, thus allowing for possible sacrificing of accuracy in the predictions of the constituent concentrations. This is especially true for mixtures. In addition, a large number of samples are normally required for accurate calibration.

## Glossary

- |                        |   |
|------------------------|---|
| Collinearity           | Approximate linear dependence among experimental variables.   |
| Cross-validation       | Concept where every object of the X-matrix is removed from the dataset once, and a model is computed with the data that remains.                            |
| Eigenvalue             | A measure of the magnitude of variation of a derived variable within a multivariate analysis technique.   |
| Latent variable        | Unobserved variables which do not necessarily have to be orthogonal.  |
| Multivariate analysis  | Statistical, mathematical, or graphical techniques that consider multiple variables simultaneously.   |
| Outlier                | A sample that does not follow the same model as the rest of the experimental dataset.   |
| Principle component    | A set of variables that encompasses the maximum amount of variation in a dataset and is orthogonal to the previous principle component of the same dataset. |
| Scree-test             | Based on the idea that residual variance levels off when the proper number of principal components is obtained.   |
| Univariate calibration | Construction of a relation between variables $x$ and $y$ , such that $x$ can be used to predict $y$ .   |
| Variance scaling       | Variance scaling is used to emphasize small variations in the data by giving all values equal weighting.  |

## Expert Systems

M J Adams, RMIT University, Melbourne, VIC, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Expert systems constitute a branch of artificial intelligence and the name is often considered as synonymous with the term knowledge-based systems. They are computer programs; software products that attempt to replicate the knowledge and skills of a human expert in a specific domain in order to solve problems.

Early computerized intelligent systems, belonging to the so-called first generation of intelligent programs, concentrated on attempts to code general problem-solving strategies. Knowledge about any specific problem being solved was integrated, often buried, within the program code. Results obtained required tedious analysis and interpretation and generally little progress was made in applying such systems to real-world problems.

Second-generation programs represented a significant advance in user friendliness. This was largely achieved by separating the procedural, reasoning part of the code from a database containing data and information relevant to the specific problem. Such programs are typified by DENDRAL (used to infer plausible molecular structures from mass spectra and nuclear magnetic resonance data) and are interactive and flexible in terms of user communication.

Subsequent development and progress in expert system technology built on this scheme of keeping data/information and processing functions separate. Other improvements included enhanced flexible reasoning models and greatly improved interactivity and user communications with regard to the programs explaining their line of reasoning and being capable of interrogation about processes undertaken.

Once it was realized and accepted that expert systems worked best on problems limited to a specific domain, then a considerable number of applications of such systems in analytical science rapidly developed. This is particularly the case in automating the interpretation of spectral data. The apparently obvious correlation or correspondence between a spectral pattern and its parent molecular structure has proved to be an attractive and fruitful field for researchers developing expert system technologies and applications. Initially mass spectrometry, and later infrared (IR),  $^1\text{H}$ , and  $^{13}\text{C}$  nuclear magnetic

resonance (NMR) spectroscopies have all been domains in which expert systems have been developed. The scientific literature contains many hundreds of papers detailing their development and application. In addition to interpreting single-source data, many attempts have been reported that seek to combine sample spectral data from multiple sources. The early work on expert systems in analytical science led to much debate on the usefulness of expert systems in chemistry and today most reported applications are more modest in scope and tend to be focused on a specific application.

### Structure of Knowledge Base Systems

A general characteristic of expert systems is the separation of the domain knowledge, i.e., knowledge specific to a problem domain (e.g., IR spectra or proton NMR spectra), from the program's operational processes that are contained in an inference engine (Figure 1).

#### The Knowledge Base

The knowledge base holds facts, which may comprise short-term and long-term information, and rules, which can be considered as long-term information, on how to generate new facts. Within the knowledge base information can be represented in a number of ways, including predicate calculus, frames, semantic networks, and production rules.

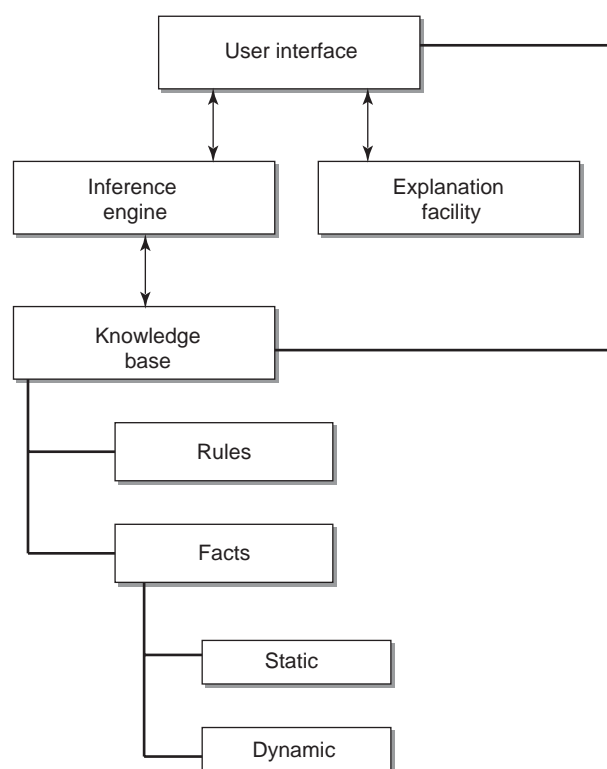

Predicate calculus is derived from propositional logic, in which propositions or statements can result in one of two values, e.g., true or false. Several logical operators exist to enable propositions to be developed. Some of the most important are:

- logical AND ( $\wedge$ ),
- logical OR ( $\vee$ ),
- negation NOT ( $\sim$ ),
- implication ( $\rightarrow$ ), and
- equivalence ( $\leftrightarrow$ ).

Statements can be developed using operators such as 'for all' ( $\forall$ ) and there exists ( $\exists$ ) and combining such operators can provide a modular, precise, and abstract representation of interpretation strategies. For example, the interpretation of a X-ray fluorescence (XRF) spectrum could include the statement,

$$(\forall x, y) \text{PeakAt}(x, 57.5) \wedge \text{PeakAt}(y, 51.7) \\ \rightarrow (\exists z) \text{Iron}(z) \wedge \text{Present}(z) \quad [1]$$

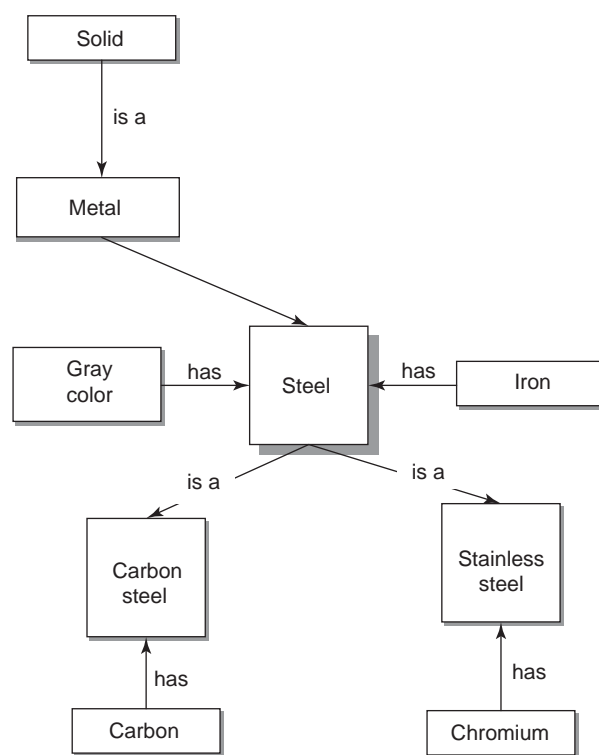

**Figure 1** The modular structure of an expert system separates the reasoning process (the inference engine) from the specific domain information (the knowledge base) comprising both rules and data. The explanation facility provides a means of tracing the reasoning scheme during or after an analysis.

This can be interpreted as stating that a pair of peaks occurring at angles of  $57.5^\circ$  and  $51.7^\circ$  in the dispersion spectrum implies iron is present in the sample giving rise to the spectrum.

Semantic networks and frames are similar structures for storing information. Networks use nodes, generally containing a single piece of information, linked to other nodes by relationship arcs. Semantic networks have a less formal and rigid structure than frames that are used to describe hierarchical data. A frame may contain several slots, each holding data or initiating an action if the value in the slot changes. An important feature and characteristic of these structures is the property of inheritance; objects or frames automatically assume the characteristics associated with their parent frame in addition to the specific information contained in their own slots (Figures 2 and 3).

Production rules, also known as 'if-then' pairs or condition-action pairs, form the basis of rule-based expert systems. They resemble implication statements in predicate calculus and can not only generate new facts, but can also run other programs, activate or deactivate other rule-sets, and even change the

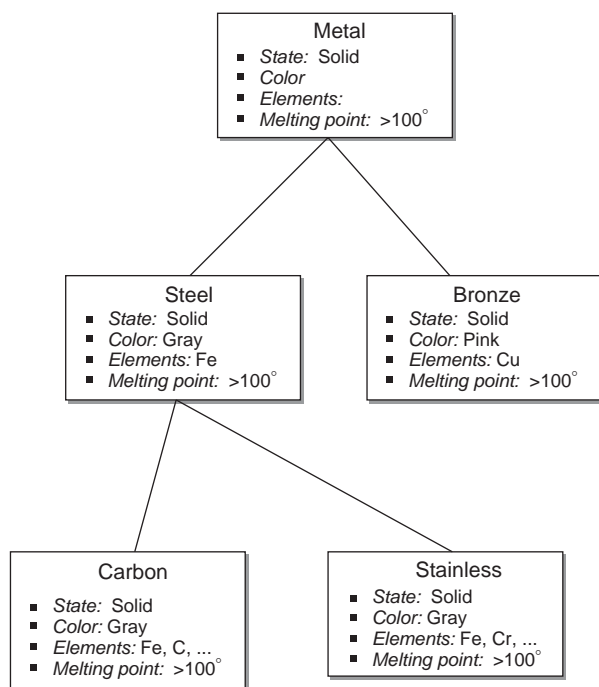

**Figure 2** A semantic network is a collection of objects and relationships and is used to represent knowledge. Whilst more flexible than frame structures (Figure 3), their poor formal representation can complicate the operation of the inference engine.

context of inference. Rules are usually independent of each other, making construction and editing of new rules simple, and their use imposes a uniform structure on the knowledge base. They are often a natural way of expressing certain knowledge, but in a complex system they can be difficult and confusing to trace (Figure 4).

### The Inference Engine

The data and information in the knowledge base are processed by the inference engine, the part of the expert system containing the general problem-solving strategy. The inference engine uses production rules and facts held in the knowledge base to infer new knowledge. The scheme can be backward driven, forward driven, or a combination of both.

Forward- or data-driven inferencing starts with known facts and using rules derives new facts that are themselves stored in the knowledge base. The inference engine iterates this operation until no new facts can be inferred or some specified goal is achieved. Forward chaining will infer everything that can be inferred from the data provided, and this process can result in unfocused questioning

**Figure 3** Frame-based representation of knowledge provides a hierarchical format. Like semantic networks the nodes, or frames, can contain multiple pieces of information in slots, and are linked according to defined relationships between two or more objects. An important property of the frame structure is the ability for frames to inherit slot values. Thus, *Steel* inherits its *state* value from the *Metal* frame.

**Figure 4** Production rules are the most common formal form of knowledge representation. Rules are easily understood with each rule representing a single piece of knowledge, and they can be easily added to, removed from, or modified in a rule base.

when further information is requested from a user (Figure 5).

Backward-driven inferencing, or goal-driven inferencing as it is sometimes called, involves starting with some goal or specific fact (e.g., 'is lead present in the sample' or 'is a carbonyl functional group indicated by an IR spectrum') and determines which rules will satisfy this goal. This backward-chaining process is repeated until all necessary subgoals are resolved and a value for the primary goal derived.

Backward-driven inferencing is very efficient in determining a specific answer, but not as good or effective at general reasoning (Figure 6).

Since both inference strategies have advantages and disadvantages, most successful systems, and commercially available shells, generally incorporate both schemes.

## User Interface

In addition to the knowledge base and inference engine, an expert system should include an explanatory interface. Its purpose, as its name suggests, is to provide the developer or user with an account of the reasoning strategy employed. Important reasons for a system having an efficient and effective explanation facility are

- to demonstrate to the user that the results presented are reasonable;
- to instruct or train new users about the knowledge in the system; and
- to aid development and debugging.

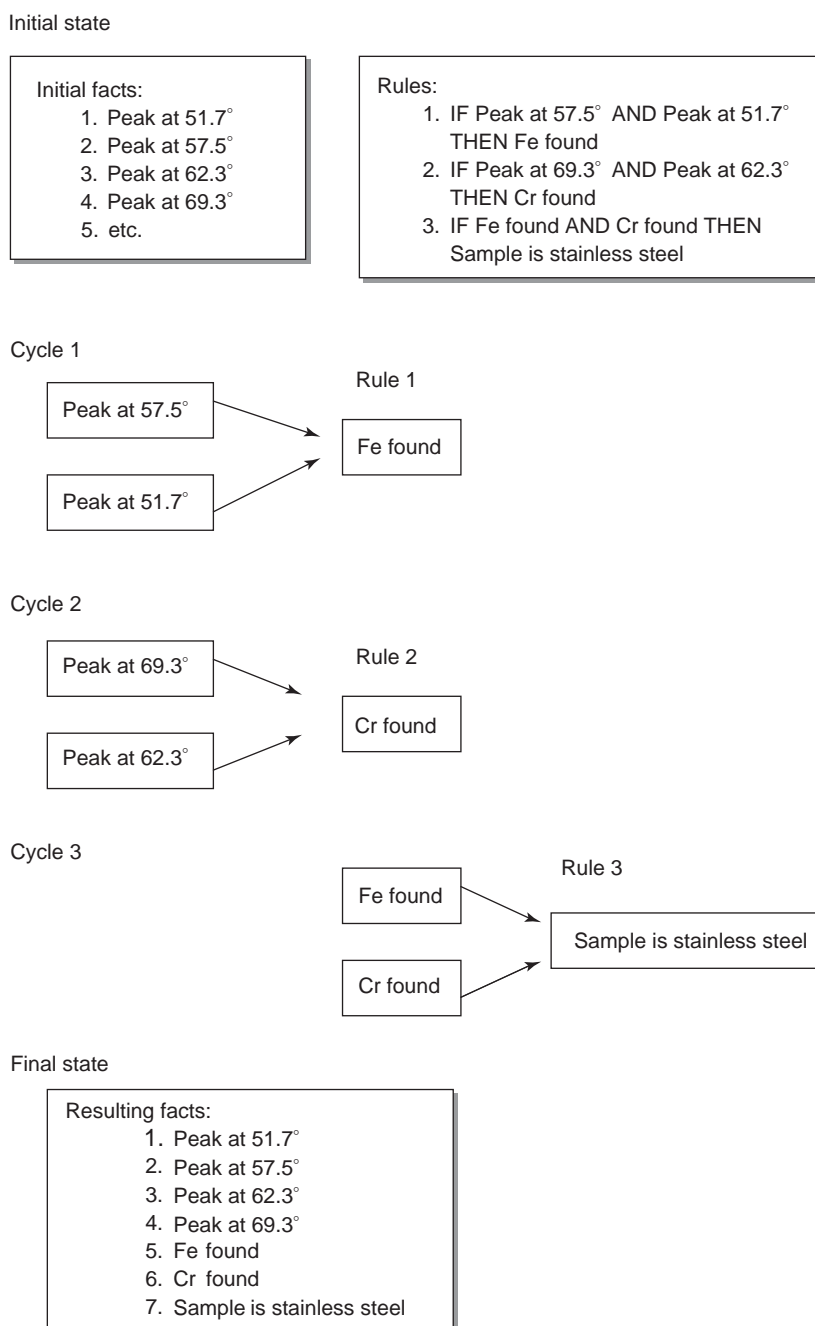

It is generally accepted that most current expert systems described in the literature or available commercially are relatively primitive in their ability to explain the reasoning involved in reaching a conclusion.

The interface with the user is an important and significant part of an expert system. An expert system's task is not necessarily complete when a question is answered or a problem solved; the system must be capable of explaining its reasoning and display how conclusions are attained. The importance of this explanation facility should not be underestimated. A user may be a novice in the domain in which the system operates, and it can have, and manipulate, knowledge outside of the competence of the user. For a user to trust and confidently act on the decisions and results proposed by an expert system its operations and strategies must be transparent.

## Expert System Implementation

Developing and implementing an expert system requires the use of a computer language or development tool. The programming languages used for expert system applications are generally either problem-orientated languages such as BASIC, FORTRAN, PASCAL, or C, or symbol-manipulation languages such as LISP or PROLOG. Although symbolic programming languages were developed specifically for applications in artificial intelligence, the

**Figure 5** The forward-chaining scheme initiates the search for a goal by sequentially firing all rules until either a goal is found or no rule fires. In this much-simplified example, the system is presented with a peak list from an XRF spectrum and using simple production rules can infer that the sample is a stainless steel.

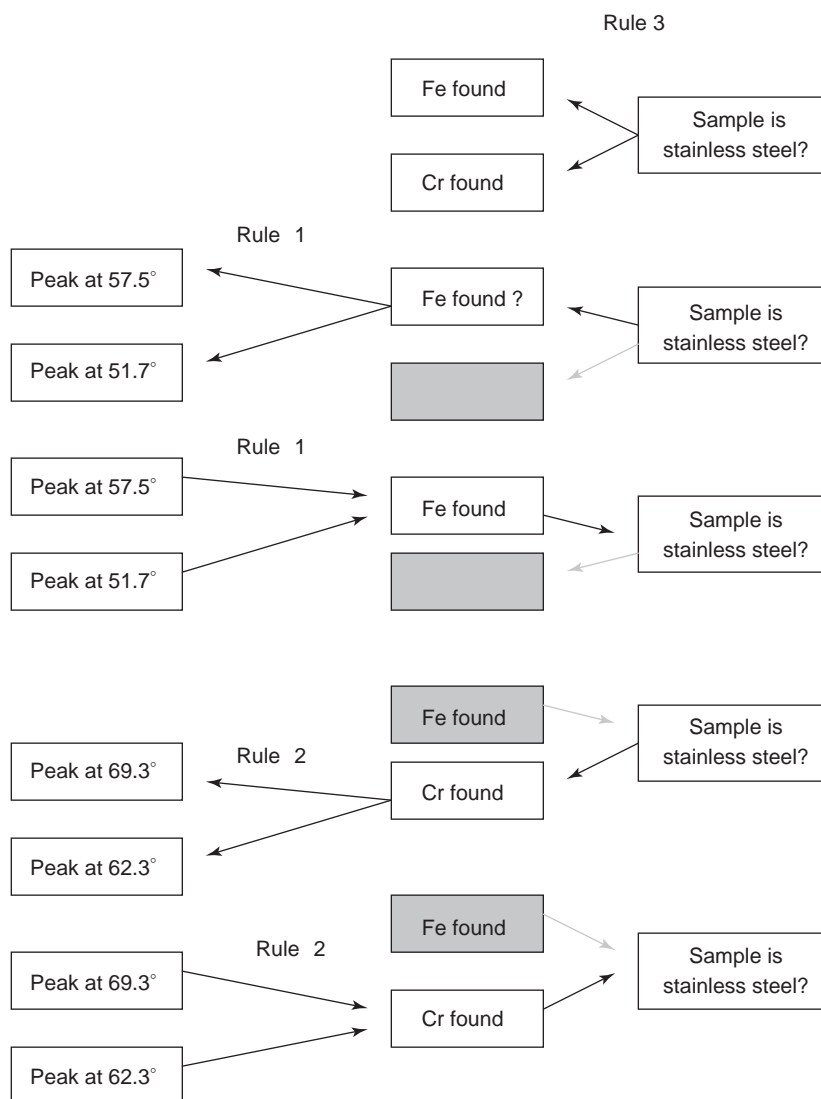

vast majority of expert systems are implemented in the more traditional problem-orientated languages.

It is not uncommon for developers of expert systems to use programming tools, knowledge engineering languages referred to as shells, specifically designed for this purpose. Shells include a number of features common to all expert systems, including an inference engine, a predefined rule language, a user interface, and a development interface. A number of

such shells are available commercially and their use can considerably aid the development and application of expert systems.

## Uncertainty in Expert Systems

Many applications of expert systems in analytical science have to cope with and manage situations

**Figure 6** Backward chaining starts with the goals and initiates the firing of rules according to the question asked. It is a commonly employed technique where the volume of data is large. Here the question 'is the sample a stainless steel' is answered by seeking confirmation for the presence of both iron and chromium in the XRF peak list.

involving uncertainty that may arise from imperfect domain knowledge or imperfect data. Although it is generally agreed and accepted that uncertainty is an important aspect of expert system reasoning strategies, there is little general agreement as to how it is best implemented. Some common and well-documented methods include probability theory, certainty factors, and fuzzy logic.

Conditional probability is based on Bayes' rule that may be simply represented as

$$P_{(H|E)} = \frac{P_{(E|H)} \cdot P_{(H)}}{P_{(E)}} \quad [2]$$

$P_{(H|E)}$  is read as the probability of hypothesis  $H$  given that evidence  $E$  exists.  $P_{(E|H)}$  is the probability

of evidence  $E$  being observed given hypothesis  $H$ ,  $P_{(H)}$  is the probability of  $H$  in the absence of evidence  $E$ , and  $P_{(E)}$  is the probability associated with evidence  $E$ . Although eqn [2] is adequate for a single hypothesis, when a number of competing hypotheses exist each has to be considered in the calculation of  $P_{(H|E)}$ . A more generalized form of Bayes' rule is

$$P_{(H_i|E)} = \frac{P_{(E|H_i)} \cdot P_{(H_i)}}{\sum [P_{(E|H_i)} \cdot P_{(H_i)}]} \quad [3]$$

The need to include all hypotheses in the calculation is the main weakness of this approach in handling uncertainty.

Some of the problems associated with using Bayesian probability are overcome by the implementation

of certainty factors (CF). A certainty factor can assume a value in the range  $-1$  to  $+1$ , representing the conditions of certainly false to certainly true. The system can link evidence to hypotheses using production rules of the form,

$$\begin{aligned} &\text{IF evidence } E_1 \wedge E_2 \wedge \dots E_n \text{ THEN hypothesis} \\ &H_i \text{ is true, certainty } C_i \end{aligned} \quad [4]$$

The value of  $C_i$  is derived from CF values of the evidence weighted by the CF factor associated with the rule:

$$\begin{aligned} &CF(H_i, E_1 \wedge E_2 \wedge \dots E_n) = CF(\text{rule}) \\ &\times \min[CF(E_1), CF(E_2), \dots, CF(E_n)] \end{aligned} \quad [5]$$

This scheme can model uncertainty or errors associated with both imperfect data ( $CF(E_1) \dots CF(E_n)$ ) and imperfect domain knowledge ( $CF(\text{rule})$ ). Adoption of the scheme assumes that the conclusion of one rule is independent of the conclusion of other rules.

Fuzzy logic is derived from fuzzy set theory. It has received considerable attention in the scientific literature and has been associated with a number of expert systems in analytical science. Traditional set theory declares an object as either a member of a class or not, there is no ambiguity. Data interpretation, however, is often ambiguous and in practice a class may not have a clearly defined boundary. For example, inspection of an IR spectrum may unambiguously indicate the presence of a carbonyl group in a sample, but characterizing the band as originating from a ketone or ester will be less certain. Fuzzy set theory allows objects to have a possibility of membership to a class. The value of this membership ( $\mu$ ) can range from 0 (no membership) to 1 (definitely a member). Consider the apparently simple task of identifying a single peak in a spectrum. A common approach is to compare the position (expressed as wavelength, frequency, angle, etc.) of the recorded peak to a reference table to find a suitable match. The problem is defining an acceptable match. Is a difference in position of one unit acceptable or must the difference be zero? The problem can be overcome by replacing the fixed, crisp value of the peak position by a fuzzy value defining the likelihood of acceptance (Figure 7).

The three basic operators for fuzzy sets are complement, union, and intersection:

$$\begin{aligned} \mu_{\bar{A}}(x) &= 1 - \mu_A(x) \\ \mu_{A \cup B}(x) &= \max[\mu_A(x), \mu_B(x)] \\ \mu_{A \cap B}(x) &= \min[\mu_A(x), \mu_B(x)] \end{aligned} \quad [6]$$

**Figure 7** A triangular function centered about a spectral line reference value provides for uncertainty and error when matching a measured value to the reference value. The further the measured value is from the reference value, the less the match strength as given by its membership value,  $\mu$ .

**Figure 8** Multiple recorded spectral lines can be matched to reference values by recording the intersection of each with the membership function associated with each reference value. An overall match value can be gained by, for example, averaging the membership function values for each line.

where  $\mu_A(x)$  is the membership function (possibility) value for object  $x$  being in class  $A$ .

An important aggregation operator is defined by the arithmetic mean ( $h$ ),

$$h(\mu_1, \mu_2, \dots, \mu_n) = \frac{\mu_1 + \mu_2 + \dots + \mu_n}{n} \quad [7]$$

Application of such aggregation operators permits, for example, the matching of multiple recorded lines to reference lines by fuzzifying the observed peak positions (Figure 8).

## Knowledge Acquisition

Acquiring and eliciting the data and knowledge required by an expert system and structuring such

knowledge into a useable form is a primary bottleneck in expert system development. Rarely can the process be automated and few tools exist to aid the process.

Knowledge for an expert system can originate from many sources, including text books, databases, case studies, personal experience, and empirical data. Usually, the main source of knowledge is the domain expert and information is obtained through direct interaction with the human expert, at a prolonged series of intense, systematic interviews. The so-called knowledge engineer will present the expert with both model and realistic problems to solve typical of the problems the expert system will be expected to deal with. Domain experts often have great difficulty expressing their problem-solving strategies in a structured manner. Where a machine can be seen to solve problems in a piecewise manner, building on simple information in a stepwise manner to reach a more complex judgment, a human expert will seldom be seen to operate at a basic level. The expert will often make complex judgments rapidly. Pieces of basic knowledge are assumed and combined so quickly that it may be difficult for the expert to recognize or describe the process. Information may appear to be neglected and a complex reasoning process simply passed off as intuition. It is what to consider basic and relevant that makes such a person an expert.

Psychologists and management scientists have studied experts and their problem-solving techniques, using both observational and intuitive methods to measure performance and disclose expertise. Whatever methods are used, and most applications employ a wide range of techniques for acquiring the required knowledge, the process is likely to be the most time consuming and expensive part of developing the expert system.

## Expert Systems in Analytical Science

Expert systems have been extensively applied in many branches of analytical science, and in a number of noteworthy cases (generally involving molecular structure elucidation from spectroscopic data) such applications have led to the development of the technology. In addition to organic, molecular spectroscopy automated spectral interpretation systems have also been developed for X-ray diffraction, X-ray fluorescence, and, as advisors for instrument optimization, for atomic absorption spectrometry.

In chromatographic and separation science considerable investment has been made in advisory

systems for selecting the best column and conditions for a specific analysis. An interesting development of some of these systems is that they can have the ability to search online scientific literature for appropriate information.

Expert systems can be embedded within analytical instruments, to monitor equipment performance, report defects and errors, and in some cases provide maintenance and repair help to users.

The advent and implementation of laboratory information management systems has provided many opportunities for expert system technologies. Prioritizing samples and instruments and scheduling workloads can be undertaken using expert systems, in addition to summarizing and reporting on the analytical results obtained.

A well-developed explanation facility and a good user interface provides expert systems with a valuable role for training and instructing novice users of the analytical technique.

In addition to providing advice and recommendations, expert systems can be extended to act on their own results by controlling, for example, instrumentation or process plant. Since such real-time operations require decisions within a fixed, and often limited, timescale, restrictions may be imposed on the way such expert systems function. Intelligent control of instruments in industrial plants is growing. The speed and quantity of data produced by modern instrumentation outstrips the rate at which humans can process and respond to it. An advisory expert system may contain many thousands of pieces of information but the majority of this will be static and change only slowly. A control expert system, in contrast, can contain a considerable amount of both fixed and variable information about its environment. Data may change substantially within a very short period of time and the expert system must be capable of not only accessing these data but also responding to them.

The value of an expert system depends on the quality (both accuracy and completeness) of the data it contains, as well as the sophistication of the shell or inference engine. As computer power grows and instrumentation becomes more automated, the development of larger and better knowledge bases will continue and the application of expert systems will become more evident.

## Introduction

The name 'chemometrics' was first used by Svante Wold in a Swedish journal. In general, it refers to a chemical discipline that focuses on maximizing the extraction of information from data and experimental measurements with the aid of mathematical, computational, and logic methods. The data or information collected are submitted for analysis by one or more methods of chemometrics typically associated with pattern recognition, classification, or prediction.

A detailed discussion of these three common chemometrics methods may be found elsewhere in this Encyclopedia or in compendia such as that by D.L. Massart *et al.* In general, they provide a backdrop against which the concepts and contributions of the multicriteria decision-making methods (MCDM) may be compared and understood.

Raw data are normally arranged in matrix form with rows representing objects, such as samples, spectra, chromatograms, and columns representing variables, such as different chemical, physical, or biological characteristics of objects, spectral frequencies or wavelengths, and time. Thus, chemometrics facilitates the interpretation of multivariate systems generally collected in two-dimensional data matrix format although multiway methods of data presentation are also available. Clearly, chemometrics relies on fast computational processes, and as a discipline did not seriously appear on the agenda of analytical

chemistry until the 1970s when sufficiently fast desktop computers became more common. Since that time, thousands of scientific investigations and practical industrial or laboratory applications have been reported and utilized. These range, for example, from the classical rapid near infrared spectroscopic determination of properties of wheat or petroleum products to the more recent simultaneous spectrophotometric determination of several metal ions present in real-world electroplating solutions or the simultaneous kinetic-spectrophotometric determination of carbamate pesticides with the aid of three-way data unfolding.

There are significant advantages in using the multivariate approach:

- Chemometrics methodology is often able to model quite complex responses consisting of many overlapping signals from individual analytes.
- The ability to predict simultaneously, concentrations or property values of several analytes from one measured response obtained from a mixture of the analytes.
- Requirement for sophisticated and costly instrumentation can sometimes be replaced by quite inexpensive methods, the performance of which is enhanced with respect to data interpretation and calibration modeling by chemometrics.

In the context of analytical chemistry, these advantages are well illustrated in recent studies such as the simultaneous determination of five metal ions found in electroplating solutions, with the use of visible spectrophotometry and chemometrics and the simultaneous kinetic-spectrophotometric determination of carbamate pesticides.

## Multicriteria Decision Making

**S Kokot and G A Ayoko**, Queensland University of Technology, Brisbane, QLD, Australia

## Introduction

The name 'chemometrics' was first used by Svante Wold in a Swedish journal. In general, it refers to a chemical discipline that focuses on maximizing the extraction of information from data and experimental measurements with the aid of mathematical, computational, and logic methods. The data or information collected are submitted for analysis by one or more methods of chemometrics typically associated with pattern recognition, classification, or prediction.

A detailed discussion of these three common chemometrics methods may be found elsewhere in this Encyclopedia or in compendia such as that by D.L. Massart *et al.* In general, they provide a backdrop against which the concepts and contributions of the multicriteria decision-making methods (MCDM) may be compared and understood.

Raw data are normally arranged in matrix form with rows representing objects, such as samples, spectra, chromatograms, and columns representing variables, such as different chemical, physical, or biological characteristics of objects, spectral frequencies or wavelengths, and time. Thus, chemometrics facilitates the interpretation of multivariate systems generally collected in two-dimensional data matrix format although multiway methods of data presentation are also available. Clearly, chemometrics relies on fast computational processes, and as a discipline did not seriously appear on the agenda of analytical

chemistry until the 1970s when sufficiently fast desktop computers became more common. Since that time, thousands of scientific investigations and practical industrial or laboratory applications have been reported and utilized. These range, for example, from the classical rapid near infrared spectroscopic determination of properties of wheat or petroleum products to the more recent simultaneous spectrophotometric determination of several metal ions present in real-world electroplating solutions or the simultaneous kinetic-spectrophotometric determination of carbamate pesticides with the aid of three-way data unfolding.

There are significant advantages in using the multivariate approach:

- Chemometrics methodology is often able to model quite complex responses consisting of many overlapping signals from individual analytes.
- The ability to predict simultaneously, concentrations or property values of several analytes from one measured response obtained from a mixture of the analytes.
- Requirement for sophisticated and costly instrumentation can sometimes be replaced by quite inexpensive methods, the performance of which is enhanced with respect to data interpretation and calibration modeling by chemometrics.

In the context of analytical chemistry, these advantages are well illustrated in recent studies such as the simultaneous determination of five metal ions found in electroplating solutions, with the use of visible spectrophotometry and chemometrics and the simultaneous kinetic-spectrophotometric determination of carbamate pesticides.

Alternatively, MCDM methods are principally concerned with selection, optimization, and decision-making. The bringing together of chemometrics and MCDM methods so as to maximize information from a set of data has been an interesting, useful, and expanding endeavor in chemistry.

## Role of Decisions

Making decisions intuitively, subjectively, or objectively is the experience of every human being. We make decisions when we have fun, when we are at work, at leisure, or when threatened, to give but a few examples. We ask such questions as: am I comfortable? Is this correct? Should I spend this money? And if I do what happens to some other scenarios contingent on finances? We make many of our decisions qualitatively. Recently, Brans discussed this problem in the context of the Natural Real World, and it was noted that the human species developed an approach for making decisions, which is based on measurement and modeling. However, mathematical models are developed in virtual space and are usually approximations of reality. Consequently, there is always a role for the decision-maker. This implies that a degree of subjectivity is used to modify the mathematical model, which is regarded as the rational solution. Interestingly, three elements of thought are incorporated into the decision-making process – rationality, subjectivity, and ethics. It is in this context that the MCDM models are broadly considered today and applied to a huge variety of problems, e.g., comparison of performance of baseball teams, development of negotiation support systems, selecting landmine detection strategies, etc. Of particular interest is a study that investigated the contribution of the MCDM methods for decision support systems. Over 20 studies involving a variety of problems and methods were investigated, and the outcomes of each study were formally analyzed with respect to the contribution of MCDM analysis.

All of the above illustrations are outside the realm of analytical chemistry and instrumental analysis, which are vital for qualitative and quantitative definition or description of scenarios in environment, agriculture, civil engineering, medicine, and similar fields of scientific and technological endeavor. Since chemical data derived by analytical methods are critical for decision-making in these fields, many examples of the applications of MCDM can be found in such fields. One important common element in decision-making in these fields is that it is becoming more and more multidisciplinary, i.e., several disparate stakeholders, such as administrators, scientists,

technologists, doctors, contribute to the outcome of the decision-making process, and, thus, the solution sought is a compromise. Some MCDM methods facilitate the analysis of such multidisciplinary scenarios by providing valuable guidance to the final decision, in which the decision makers ultimately have the final choice.

## Comparison of Some MCDM Methods

MCDM methods commonly offer partial preordering as well as net full ordering or ranking of objects. The latter ordering method is well known. The objects are simply lined up according to some index either top-down (largest index value is preferred; sometimes referred to as maximized ranking) or bottom-up (the smallest index value is preferred, i.e., minimized ranking). Partial preordering, on the other hand, is less common. It is concerned with the situation where objects may perform equally well but on different variables, i.e., they cannot be compared and one object cannot be preferred to others. When this occurs, such objects are alternatives. The simple matrix in Table 1 illustrates these concepts.

From Table 1, it can be clearly seen that O1 is the preferred object (highest row sum) while O4 is the worst performing one (lowest row sum); O2 and O3 have the same row sums, which are derived from different variables. Hence, these two objects cannot be compared, and are therefore alternatives. The partial preorder of objects 1–4 may be represented as O1, (O2/O3), O4 ('maximized' ranking). If the criterion was reversed, i.e., the lowest row sum was preferred ('minimized ranking'), then the rank order would also be reversed, O4, (O2/O3), O1.

Some common MCDM methods include PARETO, elimination et choix traduisant la réalité (ELECTRE), simple multiattribute ranking technique (SMART), ORESTE, NAIADE, preference ranking organization method for enrichment evaluation (PROMETHEE), Hasse diagram technique (HDT), multiple attribute utility theory (MAUT), and analytical hierarchy process (AHP). For details of their algorithms, differences, and refinements the reader is

**Table 1** Matrix illustrating ranking concepts (preference criterion: highest row sum preferred)

Objects	Variables				Row sum
	V1	V2	V3	V4	
O1	1	1	1	1	4
O2	1	0	1	1	3
O3	1	1	0	1	3
O4	0	0	0	0	0

referred to the primary literature, a start to which may be made with the references from the 'Further Reading' section. The central aspect of these methods is that they are designed to provide a method of comparison in terms of performance or preference of one object to another. The methods provide this information in different ways, e.g., ELECTRE and PROMETHEE are outranking methods, AHP gives a priority of alternatives. Some methods provide a full outranking order of objects, and others also give their partial preorder, which reflects their incomparability. A visual display of the rankings with the aid of line diagrams is sometimes available to indicate the rank order as illustrated in **Figure 1**. This mode of presentation is particularly useful because many people from different backgrounds can easily relate to pictorial information relative to equivalent numerical presentation. This is important because quite often decisions have to be explained to participants or decision makers with different educational backgrounds.

There are no universal methods for comparing the performance of MCDM methods. However, there have been many studies concerned with the selection of the most appropriate MCDM method. In one substantial study, Al-Shemmeri *et al.* evaluated the performance of 16 MCDM methods to solve a multicriteria water resources problem. The methods were rated on the basis of 24 criteria spread more or less evenly over four categories such as characteristics describing (1) the problem, (2) the decision maker, (3) the techniques, and (4) the solution obtained. PROMETHEE was declared the best performing method. However, in another study concerned with the ranking of chemical substances, and focusing on the relatively recent MCDM approach, the partial preorder HDT, Lerche *et al.* found that this method was to be preferred over others including PROMETHEE. The latter method, nevertheless, ranked well ahead of methods such as NAIADE, ORESTE, and AHP. The important criteria for

method comparison in this case were the minimization of subjectivity and facilitation of method transparency, i.e., the role of the decision maker was minimized. Others have argued that the real world is about risks and balances and strongly involves the decision maker. Therefore, provision for the inclusion of subjectivity, ethics, as well as the rational contributions from science and technology is important. Three MCDM methods regarded by Salminen *et al.* to be particularly suitable for application to environmental problems, SMART, ELECTRE III, and PROMETHEE, were compared, and it was found that there was little difference between PROMETHEE and SMART, but it would seem that ELECTRE III had some extra functionality. Interestingly, others regard PROMETHEE to be more refined than ELECTRE in that the former method quantifies the degree of preference by estimating a global preference index of an object compared with another for each criterion. The consistent general conclusions from such method comparison studies suggest that:

- there is no unique best MCDM method;
- the decision maker is always an important contributor to the MCDM process; and
- it is useful to apply more than one MCDM method to find the compromise solution to the problem.

## MCDM Methods and Chemometrics

As indicated in the previous sections, the scope of application of MCDM methods is generally huge. This is in contrast to their applications in chemically related fields such as analytical chemistry and similar fields where chemical criteria play a significant role. In general, the qualitative exploratory principal component analysis (PCA) and the quantitative prediction of analytes have dominated analytical chemistry by multivariate calibration methods. Other chemical fields have followed more or less similarly although MCDM methods have found significant application in the environmental chemistry area. This is probably so because there is a substantial need to involve multidisciplinary teams and criteria in the resolution of environmental problems. In addition, there are usually many stakeholders and decision makers that provide inputs to find the compromise solution in such problems. Therefore, decision-making support methodologies that have the capacity and flexibility to offer diverse modeling options and include the subjectivity of the decision makers are required.

Keller *et al.* have been credited with the introduction of MCDM methods to chemometrics in 1991.

**Figure 1** Diagram for the partial preorder of the example shown in **Table 1**.

They explained the decision-making concepts with the use of data matrix containing information on the development of a chemical formulation for the treatment of textile products. PARETO Optimality, ELECTRE, and PROMETHEE partnered by GAIA MCDM methods were applied and compared. The first of these, PARETO Optimality, was found to be useful in simple bicriteria cases, while the remaining methods illustrated the more substantial multivariate approaches. ELECTRE and PROMETHEE provided similar ranking and selection information regarding the formulation. Both facilitate graphical presentation of partial and net outranking flows. However, when linked to GAIA, which is essentially a form of a PCA biplot (PC1 versus PC2), very useful additional information is provided about the rank order of the objects and particularly about the criteria, which are significant in influencing the ranking. Interestingly, the data matrix for GAIA is generated from the PROMETHEE net outranking flows, and anecdotal observations suggest that the PCA clustering from this matrix is rather crisper than that achieved from the conventionally standardized or normalized raw data matrix. It is also interesting to note that in their 1997 definitive text on chemometrics, Massart *et al.* relied heavily on the above work by Keller *et al.* in their section on MCDM. Apart from the three methods above, arguably only one other substantial method, Utility Functions, was discussed. Following Keller *et al.*'s study, PROMETHEE and GAIA have been applied to a number of chemically related areas, including the problem of selecting the most suitable microwave digestion method for the dissolution of soil samples and comparison of the quality of Australian and Vietnamese rice grains. In an in-depth study by Kokot and Phuong, which appeared in 1999, PROMETHEE models were tested on a combined matrix consisting of the chemical (elemental content), biochemical (proteins), and physiobiological (length, chalkiness) characteristics of various types of Australian and Vietnamese rice grains. More recent examples of the application of MCDM in chemometrics are illustrated by the PROMETHEE and GAIA analysis of the prediction performance of various multivariate calibration models derived from different methods of chemometrics, e.g., PLS, BP-ANN, RBF-ANN, PARAFAC, and others. Chemistry and microbiology were brought together in a further PROMETHEE and GAIA study of ranking of some organotin(IV) compounds in relation to their fungicidal properties, while several recent investigations, reported at symposia, applied the same MCDM methodology to air quality problems in homes and in relation to performance of truck engines. These MCDM methods have also been successfully used

to resolve life cycle assessment problems and to plan the development of river alluvial plains. While these examples are by no means exhaustive, they serve to illustrate the range of more recent applications of MCDM methodology in chemometrics. In addition, they demonstrate how these two versatile and well-established MCDM methods may be set up to interpret a problem and illustrate the powerful visual presentation of the outcomes.

## The PROMETHEE Model

PROMETHEE is a nonparametric method applied in Euclidian space to rank objects. Each variable in the raw data matrix is set to maximize or minimize; then the data array is converted to a difference,  $d$ , matrix. This is achieved for each criterion by comparing all values pairwise by subtraction in all possible combinations. Preference indices are computed for each  $d$  value for each object with the use of a mathematical preference function selected independently for each variable, e.g., linear function or a Gaussian. When commercial software is used, such functions are simply chosen from the selection provided but when the algorithm is written in-house then any function deemed suitable might be included. From the individual preference indices, the global preference can be computed for each object and the positive and negative preference flows,  $\Phi^+$  and  $\Phi^-$ , are calculated from these indices; the former indicates how each object outranks all others and the latter how each object is outperformed by all others. These outranking flows are compared and produce a partial pre-order according to three rules:

- i. one object is preferred to another,
- ii. there is no difference between the objects,
- iii. objects cannot be compared.

It is rule (iii) that gives rise to the alternative objects of the same rank illustrated in **Figure 1**. This type of ranking is called PROMETHEE I. If rule (iii) is removed, the net flows,  $\Phi$ , are obtained and the procedure is known as PROMETHEE II. This latter scale is intuitively more satisfying but in fact tends to be less reliable than that derived from PROMETHEE I. However, particularly when large matrices are used the PROMETHEE I diagrams become very complex and challenging to interpret, and PROMETHEE II net flows may be preferred.

## PROMETHEE and GAIA: An Example

PROMETHEE and GAIA can be applied to the matrix shown in **Table 2** in order to choose the best

**Table 2** Performance matrix for some materials

Material	Property P1	Property P2	Property P3	Property P4	Property P5	Ease of use	Cost (in \$)
O1	2.0	1.5	3.0	3.0	4.0	2.0	50.0
O2	4.0	3.0	6.0	4.0	8.0	4.0	50.0
O3	3.0	1.5	3.0	3.0	4.0	2.0	50.0
O4	2.0	1.5	3.0	2.5	3.5	3.0	30.0
O5	2.0	1.5	3.0	2.5	3.0	1.0	30.0
O6	3.0	3.5	6.0	2.5	6.0	2.0	50.0
O7	1.5	1.0	2.0	1.0	3.0	3.0	5.0
O8	1.0	0.5	0.5	0.5	2.0	2.0	5.0
O9	2.0	1.5	2.0	1.5	1.0	1.0	30.0
O10	2.0	1.5	2.0	3.0	3.0	4.0	40.0

material for a special function; for example, removal of stains from carpets.

A typical decision maker would minimally prefer materials that possess the desired properties, and are easy to use while not overtly expensive. Since no one single material obviously gives the best outcome for all of the variables, PROMETHEE can assist the decision maker in arriving at the 'best compromise' solution in this multicriteria problem.

In Table 2, 'ease of use' is rated on a five-point scale, with 5 as the best and 1 as the worst while the properties are rated on 0–10 scales. To apply PROMETHEE and GAIA to the matrix, for each variable, it must be determined whether higher or lower values are preferred, i.e., whether the variable should be maximized or minimized. Next, the appropriate preference function for each variable must be chosen from the list of six preference functions available in the commercial software. In this example, based on the premise that the best material should be, efficient, easy to use, and cost-effective, the maximized linear preference function could be selected for properties P1, P2, and P3 as well as the 'ease of use', while the minimized linear preference function is used for cost and properties P4 and P5. One of the advantages of PROMETHEE and GAIA over other comparable ranking procedures is their amenability to sensitivity analysis. Thus, weights, which indicate the priority the decision maker attaches to each variable, can be set.

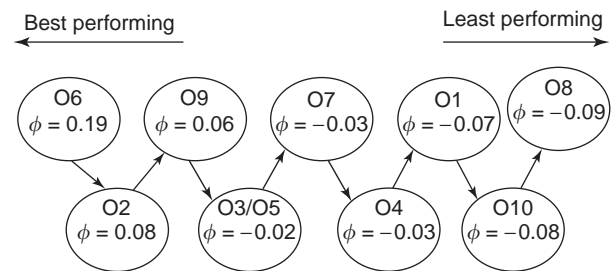

In this example (Table 2), if the decision maker attaches equal priority to all variables and they are weighted equally, the complete ranking result shown in Figure 2 would be obtained.

Thus, material O1 is the worst performing while O7 is the best performing. As illustrated by Figures 3 and 4, the ranking is sensitive to the variables considered.

It is also noteworthy that the position of the decision axis is sensitive to the weighting set for the variables (see Figures 5 and 6).

**Figure 2** Complete ranking of materials based on their properties, ease of use, and cost.  $\phi$  denotes the net outranking flow for each material: the higher its value the higher the preference of the material.

**Figure 3** Complete ranking of materials based on their properties, P, only. O8 is the worst-performing material; O6 the best-performing material, and O7 is ranked sixth.

**Figure 4** Complete ranking of materials based on their properties and cost. O1 is the worst-performing material and O6 is the best-performing material. Although the least-performing material is similar to that in Figure 3, the rank orders of the other materials varied as did the net outranking flows.

**Figure 5** GAIA plane obtained for the matrix shown in Table 2 when all variables are equally weighted; the  $\pi$  (pi) decision axis, which represents the condensed weighting of the variables, is close to the vectors for 'ease of use', suggesting that it is the most important factor influencing the ranking of the materials. A total of 87% of the data variance is accounted for by the first two principal components.

**Figure 6** GAIA biplot obtained when 'cost' is given a weighting of 5 and other variables are given unit weighting. The decision axis visibly moves toward the 'cost' axis. Vectors for properties P1, P2, and P3 are oriented in the same direction in Figure 5, suggesting that they represent equivalent information. Consequently, all three properties may be represented by P2 in this figure. Similarly, properties P4 and P5 are oriented in the same direction in Figure 5. Therefore, they may be represented in this figure by P4.

MCDM methods are powerful tools that can provide guidance for many practical problems where there are many stakeholders, and they offer extensive opportunities to extract compromise solutions, which take into considerations not only the rational findings of science and technology but also ethics and subjectivity of the decision maker.

## Signal Processing

R G Brereton, University of Bristol, Bristol, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Most analytical information is obtained in computerized form in both spectroscopy and chromatography. Signal processing is required to convert this raw digital information into graphs and numbers that are interpretable to the analytical scientist. Aims of signal processing include data reduction, integration, determining the numbers, positions, and shapes of peaks, and detection of weak signals.

The majority of analytical signals are univariate where a single response is measured normally as a function of time, although other variables such as spectral frequency or voltage can be employed. Examples include the intensity of a signal in gas chromatography obtained using a flame ionization detector as a function of time, the magnetization of a nuclear magnetic resonance spectrum as a function of frequency, and the intensity of absorbance at a specific wavelength in ultraviolet visible spectroscopy as a function of pH. Multivariate signals occur when the response is measured as a function of more than one variable, commonly two, such as diode array high-performance liquid chromatography where the intensity of absorbance of a spectrum is measured as a function of both elution time and wavelength. Higher-order signals where the response is a function of more than two variables are possible, an example is chemical microscopy where a spectrum is recorded of an image; the response is absorbance, and one of the three variables is spectral wavelength and the other two are spatial. These types of signals are illustrated in Figure 1.

### Digital Sampling

Scientific instrumentation is at the heart of the modern analytical laboratory, and the majority of information obtained is in the form of digitized signals. Conventionally, many analytical textbooks deal with analog signals, for example, such as that coming from a chart recorder, but this type of signal is rare in the modern laboratory. The output from instruments is primarily in terms of information consisting of a series of numbers, normally recorded sequentially, although some instruments, such as those containing a diode array, may collect these numbers simultaneously.

**Figure 1** Types of signals (A) univariate, e.g., the absorbance at a single spectroscopic wavelength as a function of pH. (B) Multivariate as a function of two variables, e.g., the intensity of absorbance in diode array high-performance liquid chromatography as a function of elution time and wavelength. (C) Multivariate as a function of three variables, e.g., intensity of absorbance in chemical microscopy as a function of wavelength and two spatial coordinates.

Signal processing is required to convert this raw digital information into something that is readily interpretable, normally graphically, such as a spectrum or a chromatogram. It is important to understand the digital nature of the data.

### Sampling Interval

Normally signals are sampled at regular intervals, for example, a ultraviolet/visible (UV/vis) spectrum may be sampled every nm, or a Fourier transform nuclear magnetic resonance (FT-NMR) spectrum every ms, usually the interval is regularly spaced. However, it is important always to check the units of the raw data, although, for example, mid-infrared (IR) spectra could be presented either in units of  $\text{cm}^{-1}$  or nm, generally the signals are evenly acquired in intervals based on  $\text{cm}^{-1}$ .

For multivariate signals, two or more variables are sampled; for example, in diode array high-performance liquid chromatography (HPLC) these are wavelength and time. If a spectrum is sampled every 2 nm, between 200 and 398 nm, and the chromatogram is acquired at 1 s intervals between 5 min and 6 min 59 s, then a total of  $100 (\text{wavelengths}) \times 120 (\text{points in time})$  or 12 000 datapoints are acquired.

## Sampling Window

In many forms of spectroscopy each data point is acquired over a window, rather than at a precise point. For example, in UV/vis spectroscopy a typical sampling window may be 7 nm, even if the sampling rate is smaller. This means, for example, that the spectral intensity measured at 220 nm is in fact the average intensity between 217 nm and 223 nm. This is illustrated in **Figure 2**. Many spectrometers employ windows that are large relative to sampling rates because this increases the signal-to-noise ratio, but comes at the cost of signal blurring. However, in certain other spectroscopies, such as FT-NMR, the window is by necessity small relative to sampling rate.

## Analog-to-Digital Conversion

Signals are not only digitized by recording a series of numbers usually obtained in time, but also the intensity is digitized, because the raw data have to be acquired by a computer. Computers acquire information in the form of bits, which are binary representations of integers. For example, the number 6 has a binary representation of 110 ( $= 4 + 2 + 0$ ). Any integer has a binary equivalent. However, the range of integers that can be acquired depends on the number of bits in an analog-to-digital converter (ADC): a 6 bit ADC measures a maximum range of numbers of 111 111 or  $2^7 - 1$  or 127. In many cases half the integers are reserved for negative numbers,

so a 6 bit ADC could be used to measure a range of numbers between  $-63$  and  $+63$ . Typically, ADCs consist of much larger number of bits, for example, 20 bits, which allows a range of about a million numbers. Raw readings, often in the form of voltages, are converted to these numbers by the ADC. A procedure is required to determine the relationship between raw measurement and integer value, this is usually via a receiver gain. In many instruments the size of the receiver gain is not under the control of the operator, because sensible measurements will be within a specific range; for example, in the case of UV/vis measurements, a typical range of 0.01–2 AU may be encountered in practice, outside this range spectroscopic measurements have little quantitative meaning. In other types of spectroscopies, such as NMR, there may be a wider range of measurements (e.g., dependent on concentrations of compounds) and the operator can set this parameter manually. Correct use of instruments maximizes the usefulness of the entire digital range. An ADC that is too low can result in low-intensity signals that are poorly digitized in the intensity direction, whereas one that is too high can result in overloaded signals that are cut off.

## Signals and Noise

A typical spectrum or chromatogram consists of a series of signals, usually of chemical origin, imposed upon noise. The main aim of signal processing is to obtain information about these underlying signals and remove the noise. The signals are often in the form of a series of peaks, which may correspond, for example, to the chromatographic elution profiles of a series of compounds or to electronic spectroscopic transitions. The analytical scientist usually wants to interpret these peaks both qualitatively (e.g., to identify compounds) and quantitatively (e.g., to determine the concentrations of chemical species).

## Peakshapes

Each peak is characterized by several parameters. The most usual are (1) the position of the center (which may, for example, correspond to an elution time or an  $m/z$  value), (2) the area (which may relate to concentration), and (3) the width – generally at half-height (which may provide important diagnostic information, for example, how well a chromatographic column is performing). This is illustrated in **Figure 3**. In some applications, such as chromatography, peakwidths at the base are measured, by fitting a triangle to the peak and seeing the size of the base of the triangle.

**Figure 2** Illustration of windows, for four successive samples of a spectrum centered on 220, 221, 222, and 223 nm.

Peaks can be of a variety of shapes. However, pure peaks are usually unimodal, and in most cases symmetric. The two most common shapes are Gaussian (as occurs in most types of spectroscopy and chromatography) and Lorentzian (specifically encountered in NMR). Lorentzian peaks tail more than Gaussians as illustrated in **Figure 4**. Occasionally, asymmetric peak shapes are encountered, for example, tailing chromatographic peaks as illustrated in **Figure 5**. Usually an symmetric peak shape is modeled empirically, using a Lorentzian to model the tailing half and a Gaussian the sharper half.

Typical analytical data can be represented as a sum of several such peaks. For example, a chromatogram arising from seven compounds could be modeled by a sum of seven Gaussians, each characterized by a position, width, and area, and so represented by 21 parameters in total.

### Definition of Resolution

Resolution relates to how well peaks can be characterized, and depends on the separation and widths of peaks. **Figure 6** shows two pairs of peaks both separated by an identical amount, but the top pair is less

**Figure 3** Main parameters that characterize a peak.

**Figure 4** Difference between Gaussian and Lorentzian peak-shapes.

well resolved than the bottom. There are various methods for quantifying resolution; in chromatography a popular one is to divide the difference between the peak centers by the average peak width at their base. A value of 1.5 implies excellent resolution, and one of 0.5 implies the peaks are hardly resolved.

### Noise

Superimposed on signals is noise. There are several common types of noise.

If the noise at each successive point (normally in time) does not depend on the level of noise at the previous point we call it stationary noise. There are two major types.

1. *Homoscedastic noise*. This is the simplest to envisage. The features of the noise, normally the mean and standard deviation, remain constant over the entire data series. The most common type of noise is given by a normal distribution. In most real-world situations, there are several sources of instrumental noise, but a combination of different symmetric noise distributions often tends toward a

**Figure 5** A tailing peak.

**Figure 6** Two pairs of peaks, both of identical separation but different resolution.

normal distribution. Hence, this is a good approximation in the absence of more detailed knowledge of a system.

2. *Heteroscedastic noise*. This type of noise is dependent on signal intensity, often proportional to intensity. The noise may still be represented by a normal distribution, but the standard deviation of that distribution is proportional to intensity.

Sometimes raw signals are transformed mathematically, for example, in optical spectroscopy it is usual to convert transmittance to absorbance data using a logarithmic transformation. This changes the noise characteristics, often to a log-normal distribution, although the origins of the instrumental noise are still homoscedastic.

A second type of noise is nonstationary. As a series is sampled, the level of noise in each point depends on that of the previous point. This is quite common in process monitoring. For example, there may be problems in one aspect of the manufacturing procedure, an example being the proportion of an ingredient. If the proportion is in error by 0.5% at 2 p.m., does this provide an indication of the error at 2.30 p.m.? Many such sources of noise cannot be modeled in great detail, but a generalized approach is that of autoregressive moving average (ARMA) noise. The moving average component relates the noise at the current to the values at previous times. The autoregressive component relates the noise to the observed value of the signal at one or more previous times. ARMA processes are well described in texts on time series.

### Signal-to-Noise Ratio

It is often important to measure the signal-to-noise ratio. The higher this is the easier a signal is to detect. There are a variety of methods for determining this ratio, but a common one is as follows. First, a region of the data is selected where there appear to be no signals. Then either the root mean square or the standard deviation of the data in this region is determined as an indicator of the noise level. Finally, the height of a signal is divided by the noise level.

In addition to providing a quantitative measure of the quality of spectroscopy or chromatography, this can also be used as an indicator as to whether a peak can be detected or not. If the signal-to-noise ratio exceeds 3 it is assumed that the peak is real. This is because, using a normal distribution, a value exceeding 3 standard deviations from the mean is expected in  $\sim 0.1\%$  of cases, so there is a chance of more than 99.9% that the peak is a real one, rather than originating from an artifact arising from the noise.

Signal-to-noise criteria are commonly employed as part of peak picking algorithms.

## Aims of Signal Processing

There are several important aims.

### Detection

Detection of weak signals is of significant importance. There are two reasons why a signal may be hard to detect. The first is because the noise level is high or because the amount of analyte is small, resulting in a low signal-to-noise ratio. A simple approach to overcome this limitation, possible in most types of spectroscopy where the positions of signals are quite reproducible, is time averaging. The signal-to-noise ratio increases by  $\sqrt{N}$  where  $N$  is the number of signals averaged; however, this can be impracticable in some cases, for example, if it takes 5 min to scan a spectrum it will take 500 min to increase the ratio ten-fold. Alternatives involve using smoothing functions as discussed in this encyclopedia elsewhere, or to use a faster technique for obtaining data, e.g., Fourier transform spectroscopy.

A second reason is that a minor peak may be buried within a larger one. This is common, for example, in chromatographic purity monitoring. Improving the physical measurement method (e.g., by better chromatography) is one approach, by using computational resolution enhancement functions as discussed in this encyclopedia elsewhere is also possible. If there is another dimension (e.g., coupled chromatography), it is possible to employ multivariate methods for peak purity assessment.

### Resolution

This involves determining the number and characteristic parameters of peaks in a cluster. Computational approaches are complementary to physical ones such as shimming spectrometers or changing columns. In some cases, such as NMR, the number and relative intensities of peaks in a cluster may have a precise physical meaning (e.g., a triplet implies a specific coupling mechanism), whereas in chromatography, each new component corresponds to another compound and the shapes cannot easily be predicted mathematically.

### Integration

This is one of the hardest problems in signal processing. It relates to the areas of peaks, which, in turn, can be calibrated to the concentrations and/or relative amounts of each component. The commonest

approach is to sum the intensities at each sampling point.

Many common methods for determining relative intensities result in unreliable estimates of concentrations. For example, one of the commonest difficulties relates to using signal heights rather than areas to measure intensities, because it is easier to develop signal processing software to measure heights. Only if peaks are well resolved and have identical shapes can heights be employed as a reliable approach for determining relative concentrations.

## Handling the Signal

There are several common procedures for handling digital signals as described below.

### Baseline Correction

This is a common requirement. The first step is to determine regions of baseline, as indicated in **Figure 7**; this is often done graphically, but there are also automated computational algorithms available. Next a mathematical model is fitted to these regions, which could be simple, such as an average, or more complex, such as a polynomial. This model is then subtracted from the entire dataset. In areas such as coupled chromatography it is common to fit a baseline model to the chromatogram at each wavelength or  $m/z$  value separately.

### Interpolation

Sometimes it is necessary to obtain regularly spaced data. The raw data may not be sampled regularly, for example, when studying the evolution of a process with time. In other cases it may be important to align two different types of information; an example is when using two different detectors in coupled chromatography, each of which is sampled at a slightly different rate. There are a number of methods but a simple one is as follows:

1. Establish a desired sampling interval, which is often approximately equal to the average sampling interval for the overall dataset.

2. For each interpolated sampling time, see if a real sample is obtained at exactly that time, and if so, keep it.

3. If not, take the real samples immediately before and after the desired interpolated sampling time and obtain a weighted average of the signal, the closer it is to the desired interpolated sampling time the higher the weight, so if we have signals at time 8 and 11, the interpolated signal at time 10 is two-thirds of that at time 11 and one-third of that at time 8.

### Variable Reduction

There are a large number of methods for variable reduction. In many cases the regions between peaks are of no interest. Retaining this information means storing large files; it also means that noise can dominate the analysis. Often we search for parts of the spectrum or chromatogram where there appear to be signals and reject the remainder, a common example in mid-IR spectroscopy where there are only certain discrete peaks that are interesting.

### Derivatives

Derivative spectroscopy is quite common. This involves calculating mathematical derivatives of the spectrum. The advantage is that close peaks can be resolved out. Derivatives rely on the assumption that pure peaks have only one maximum. The summation of two peaks results in a 'turning point' that can be resolved out. However, the problem is that noise is enhanced, so derivatives are often combined with smoothing functions. These methods are described in more detail in this encyclopedia.

### Resolution and Signal-to-Noise Enhancement

These techniques are described elsewhere in this encyclopedia.

## Types of Signal

There are several different types of signals commonly encountered.

### Fourier Transform Data

Such data may arise from either pulsed (e.g., NMR) or interferometric (e.g., IR) instrumentation. Data are recorded directly in the time domain. Normally, the data consist of a sum of decaying sine waves, superimposed on noise. Fourier transformation converts these into a frequency domain spectrum. For each component, the frequency of the sine wave corresponds to the position in the spectrum, the initial

**Figure 7** Typical signals with three baseline regions indicated.

intensity to the integral, the decay pattern to the lineshape (commonly an exponential decay corresponds to a Lorentzian and a Gaussian decay to a Gaussian peakshape), and the decay rate to the peak width (the faster the decay the broader the peak).

The faster a time series is sampled, the wider the spectral width in the resultant transform. The longer the time series is sampled, the greater the digital resolution in the spectrum. These parameters must be taken into account when considering the accuracy of integration. For example, a typical peak may be only a few data points wide in FT-NMR, there can be substantial distortions in peak area when a peak is characterized by only two or three data points at half-height.

The advantage of using Fourier transform spectroscopy is that data are acquired very much faster than via conventional, continuous wave, methods. This means a better signal-to-noise ratio can be achieved for an identical amount of compound in the same period of time. The increase in speed is  $\sim 50$ -fold.

#### Hadamard Transform Data

Hadamard spectroscopy is rare, but is an alternative to Fourier transform spectroscopy for improving signal-to-noise ratios. In a Hadamard spectrum, different frequencies of the raw spectrum are blocked by a 'mask'. The overall sum of intensities at the frequencies that are not blocked is then recorded. The mask is systematically changed, until several such experiments have been performed. It is possible to derive the individual spectrum from a series of experiments. The advantage is that the signal-to-noise ratio of each experiment is higher than for any individual wavelength. However, this approach has not been widely used, primarily because of the difficulty of constructing rapidly changing masks.

#### Correlation Spectroscopy and Chromatography

These approaches are quite rare. Methods for time series analysis are required to analyze the data. A signal, consisting of a time series, can be correlated with another. The resultant correlogram consists of the correlation coefficient as one series is lagged

against the other in time. Each successive lag position uses one less data point for calculation of correlation coefficients. There is a large literature on time series analysis, and the choice of number of lag positions in the correlogram is of substantial interest. The more the lag positions, the lower the signal-to-noise ratio but the greater the digital resolution.

Once the correlogram is computed, it is usually Fourier transformed. It is also possible to filter the signal at various different stages in the analysis.

#### Direct Recording

The most common way of recording spectra or chromatograms is by directly changing a sequential parameter such as wavelength or time. The result is directly interpretable without further transformation. UV/vis spectroscopy and chromatography are common examples. Considerations should, however, be given to sampling frequency and slit width as discussed above.

## Spectral Deconvolution and Filtering

R G Brereton, University of Bristol, Bristol, UK

### Introduction

Two main classes of method, univariate and multivariate, are commonly employed. Univariate methods

are as follows. Curve fitting is used when quite a good model of the individual peaks is known. Moving averages, Savitsky–Golay filters, and derivatives are simple approaches for enhancing signal-to-noise ratios and resolution of spectra. In the Fourier (time) domain, most filters involve multiplying the data by a function that can be related to moving averages via the convolution theorem. Specialized windows such as correlograms are used for time series. Finally, nonlinear approaches such as maximum entropy show great promise. Multivariate data occur in hyphenated techniques or when a series of spectra is recorded on a number of samples. Multivariate methods (sometimes called factor analysis) are useful when there is more than one measurement, e.g., hyphenated chromatography or fluorescence excitation-emission spectroscopy.

There are numerous aims of deconvolution and filtering. The simplest is to determine the number of components in a mixture. In nuclear magnetic resonance (NMR), determining how many peaks are in a cluster can tell us about the coupling pattern, and gives us diagnosis about the structure of the underlying molecular species. In pyrolysis mass spectrometry (MS), how many significant components are in a series of mixture spectra? In some areas of chromatography, detection of small peaks, e.g., in impurity monitoring, is important. Most of these questions require answers in the form of graphs rather than numerical values.

Once this qualitative information is obtained, there are a number of more quantitative questions. One of the simplest is to determine the centers or positions of each peak. In molecular spectroscopy, the position may be highly diagnostic of a specific compound. A more sophisticated problem is to pull out the spectra of each component, and in multivariate methods, to determine the chromatographic elution time, pH, or concentration profile of each component of a mixture. The individual spectra can then be compared to a library or manually interpreted. In pH equilibrium titrations, the profiles may allow determination of  $pK_a$ s.

The most difficult problems relate to quantification, normally involving integrating individual peaks or spectra arising from specific compounds. Some methods for deconvolution distort these, for example, many methods for Fourier transform resolution enhancement are dependent on peakwidths of individual components. If a spectrum consists of peaks of different widths, each peak will be enhanced to a different extent, making relative integrals meaningless. Other approaches, such as in chemometric multivariate resolution, should preserve relative integrals.

The analytical scientist has a very large battery of methods to choose from.

## Univariate Methods

### Curve Fitting

One of the conceptually simplest methods is curve fitting. The number and parameters of peaks that make up a cluster can be determined by fitting a model. Normally, this consists of a sum of well-defined peakshapes such as Gaussians and Lorentzians as illustrated in **Figure 1**. Normally, each peak is characterized by a center, a width, and a height. If there are three peaks in a cluster, then nine parameters are required to fit the data. Most algorithms are based on least squares fitting, but some newer algorithms involve imposing constraints, such as nonnegativity and unimodality.

A problem with these approaches is that the nature of the underlying data should normally be known in advance. There are many difficulties with nonlinear (e.g., Gaussian) curve fitting routines and it is sometimes hard to find a global minimum. Most computational algorithms require initial parameters, often guesses of the peakshapes, and some information about the method for iteration. In many forms of molecular spectroscopy such as NMR, where peakshapes are known with a high degree of confidence from the underlying spin physics, curve fitting routines are extremely effective. In cases such as chromatography where peakshapes are far less well established, curve fitting can be dangerous. Sometimes if only one or two parameters are varied (constrained minimization) such routines can be useful: for example, if it is desired to follow the rate of a two-component reaction by ultraviolet/visible spectroscopy, and the spectra of the pure components are well known, it is only necessary to vary a single parameter, corresponding to the proportion of each component in a mixture.

**Figure 1** Curve fitting is employed to fit the main peak into two components.

Curve fitting usually aims to represent the profile of each component separately, whereas most other methods represent the profiles in the same graph, but aims to distinguish different peaks both from each other and from the noise.

### Direct Methods: Linear Filters

**Moving averages** There are many direct methods that are used to enhance the resolution and increase the signal-to-noise ratio of peaks. One of the simplest is a moving average. A three-point moving average replaces a reading at a given point in time by the average of itself and the previous and successive points or

$$x_{i,\text{new}} = \sum_{j=-1}^1 x_{i+j} / 3$$

where  $x_i$  is the signal at point  $i$ . Noise tends to vary randomly, whereas signals vary more systematically, and are broader. Hence, the noise is smoothed away resulting in an increased signal-to-noise ratio. The number of points in the moving average filter can be increased, but is generally an odd number, often called the 'window' size. The optimum size depends primarily on the signal width. The broader the signal, the bigger the optimum size; however, as the size becomes comparable to the peakwidth in data points, peaks start to be smoothed away and so resolution and intensity is lost. **Figure 2A** illustrates a cluster of peaks and **Figure 2B** the result of three-, five-, and seven-point moving average filters. Above three points, it is evident that the data are smoothed away quite considerably. Note that it is often possible to record a spectrum or chromatogram using higher digital resolution and this may allow more powerful filters to be applied.

**Higher-order filters including Savitsky–Golay filters** It is not necessary to restrict filters to simple local averages. Often, signals are better approximated by polynomials, such as quadratics or cubics. This is especially important in the center of peaks which will inevitably be smoothed away using simple averages. Polynomial filters work by fitting a local polynomial, for example, a five-point quadratic filter will take five successive points, fit these to a quadratic model, and replace the central point by the estimated value from the quadratic model. This filter is moved along a spectrum or chromatogram. For example, the first window might involve recalculating the value of point 3 in the spectrum using points 1–5, the second window recalculates the value of point 4 using points 2–6, and so on. The extreme points of the spectrum or chromatogram are removed.

**Figure 2** (A) Raw data together with the results of (B) moving average and (C) Savitsky–Golay filters.

Because it is computationally intense to calculate fit polynomials to each point, Savitsky and Golay proposed an alternative and simpler computational method in which a new data point is expressed as

$$x_{i,\text{new}} = \sum_{j=-p}^p c_j x_{i+j}$$

where the size of the filter window is  $2p + 1$  and coefficient  $c$  can be obtained from standard tables. Different coefficients relate to window size and the order of the model (e.g., quadratic, cubic). Most

**Table 1** Savitsky–Golay filters for smoothing

Window size, $j$	Quadratic/cubic model			Quartic/quintic model	
	5	7	9	7	9
–4			–21		15
–3		–2	14	5	–55
–2	–3	3	39	–30	30
–1	12	6	54	75	135
0	17	7	59	131	179
1	12	6	54	75	135
2	–3	3	39	–30	30
3		–2	14	5	–55
4			–21		15
Normalization constant	35	21	231	231	429

filters can, in fact, be expressed in these terms and so are often called linear filters, because the new data point is expressed as a linear combination of the original data, even if the order of polynomial is greater than 1. For moving averages the value of  $c$  is  $1/(2p + 1)$ , for Savitsky–Golay smoothing functions the values are presented in **Table 1**. To calculate the coefficients, simply divide the values in the table by the normalization constant. The results of five-, seven-, and nine-point quadratic/cubic filters on the data of **Figure 2A** are presented in **Figure 2C**; the seven-point filter is about optimal, reducing noise but still preserving resolution and making it fairly obvious that this is a two-peak cluster. A nine-point filter is too extreme. Often, it is necessary to experiment using several different functions before a satisfactory answer is obtained.

There are several other linear filters such as Hanning and Hamming windows which can be found in specialist spectroscopic texts. Often, for historic reasons, users of specific spectroscopic techniques have employed particular named filters.

**Derivatives** Derivatives are frequently used to enhance resolution. The principle is that pure peaks are generally unimodal, so contain only one maximum. Peak clusters arising from several underlying components, if not completely resolved, contain inflexion points. Derivatives resolve these out, as illustrated in **Figure 3**. These also allow peak maxima and widths to be measured more easily. For example, the center of a peak has a first derivative of 0, so crosses the baseline in the derivative spectrum. It is often easier to measure a peak crossing the baseline than estimate the exact center of a flat peak. In some forms of spectroscopy such as electron spin resonance, spectra are conventionally recorded directly in the derivative mode, which allows good resolution of hyperfine

**Figure 3** Two closely overlapping peaks (top) together with their first (middle) and second (bottom) derivatives.

coupling constants. Alternatively derivatives may be calculated computationally.

There are various problems with derivatives, a major one is that noise is amplified. In order to overcome this, it is usual to smooth derivative

**Table 2** Savitsky–Golay filters for calculation of derivatives

Window size, <i>j</i>	5	7	9	5	7	9

Normalization constant	7	42	462	3	99	4 719

spectra. This can be performed by using linear coefficients as proposed by Savitsky and Golay in a similar manner to the direct smoothing. These coefficients are presented in Table 2.

### Time Domain (Fourier) Methods

Sometimes, it is useful to perform deconvolution in the time domain. In this article, time domain is used to refer to a time series and frequency domain to the directly interpretable spectrum/chromatogram. Fourier transformation is employed to transform data from the time (Fourier) domain to the frequency (spectral) domain. It is important to note that all spectra have a time domain associated with them even if directly recorded in the frequency domain.

It can be shown, for example, that a damped oscillator described by the equation

$$f(t) = A \cos(\omega t) e^{-\lambda t}$$

transforms into a Lorentzian peakshape. The value of  $\lambda$  is a time constant and influences the peakwidth. The greater its value the faster the decay rate and the broader the peak. Hence, multiplying the decay curve by a positive exponential decreases the decay rate, and so sharpens peaks improving resolution. The problem is that this process also increases the noise. Therefore, it is more usual to employ a filter containing two adjustable parameters, one to increase resolution and the other to decrease noise, a

common one being a double exponential as

$$g(t) = e^{+\kappa t - \nu t^2}$$

which is used to multiply the original time domain signal. The values of  $\kappa$  and  $\nu$  have to be adjusted and depend on noise levels and peakwidths. There are a wide variety of alternative filter functions in the literature but most depend on two adjustable parameters.

After applying filter functions, it is normal to Fourier transform the data. Sometimes for data recorded directly in the frequency domain, it is possible to perform Fourier self-deconvolution. This involves inverse transforming the spectrum or chromatogram back into a time domain, applying the filters, and then forward transforming to the frequency domain as illustrated in Figure 4.

### Convolution Theorem

Both methods for time domain (Fourier) and frequency domain (direct) filters are equivalent and are related by the convolution theorem, and both have similar aims, to improve the quality of spectroscopic or chromatographic or time series data. Two functions,  $f$  and  $g$ , are said to be convoluted to give  $h$ , if

$$h_i = \sum_{j=-p}^{i=p} f_j g_{i+j}$$

**Figure 4** Principles of Fourier self-deconvolution.

Convolution involves moving a window or digital filter function (such as a Savitsky–Golay or moving average) along a series of data such as a spectrum, multiplying the data by that function at each successive data point. A three-point moving average involves multiplying each set of three points in a spectrum by a function containing the values (1/3, 1/3, 1/3), and the spectrum is said to be convoluted by the moving average filter function. Filtering a time

series, using Fourier time domain filters, however, involves multiplying the entire time series by a single function, so that

$$H_i = F_i \cdot G_i$$

The convolution theorem states that  $f$ ,  $g$ , and  $h$  are Fourier transforms of  $F$ ,  $G$ , and  $H$ . Hence, linear filters as applied directly to spectroscopic data have their equivalence as Fourier filters in the time domain. In other words, convolution in one domain is equivalent to multiplication in the other, which approach is dependent largely on computational complexity and convenience. For example, both moving averages and exponential Fourier filters are easy to apply, one applied direct to the frequency spectrum and the other to the raw time series. Convoluting a spectrum with the Fourier transform of an exponential decay is a difficult procedure and so the choice of domain is made according to how easy the calculations are.

### Time Series Methods

In a small number of areas such as correlation spectroscopy, time series analysis is necessary. These methods have been used for many years, especially in economics, geology, and engineering, where noisy time series are recorded. This involves computing what is called a correlogram. The way this is performed is by taking a time series, and shifting it against itself by an amount called a lag, then the correlation coefficient is calculated between the original time series and the lagged series. For example, if a time series is recorded over 50 data points and lagged by 5 data points, then points 1–45 of the original time series is compared to points 6–50 of the lagged series (the last five points are lost). Lags can be both positive and negative.

There is a limit to the number of lag positions, because if the lag is too much, there are not many points remaining, a good guide is to employ around half the data points from the original time series. A graph of the correlation coefficient versus lag is called an autocorrelogram and is symmetric around a lag of 0. This is illustrated in **Figure 5** for a typical time series. The correlogram can be further manipulated by Fourier transformation, smoothing, and filtering if necessary. The aim is primarily to emphasize cyclical signals from others. The technique is especially useful when there is correlated noise.

It is also possible to compare two different time series, a similar procedure is used to compute a cross-correlogram where each time series is lagged against one another. This correlogram is no longer symmetric. It may be useful if, for example, we record a

**Figure 5** A time series (top) together with its autocorrelogram.

reference signal from a particular compound and want to see whether it is present in an experimental dataset. The time series from the pure component is cross-correlated with the experimental one.

### Nonlinear Deconvolution, Including Maximum Entropy

All the methods for filtering described above are linear; that is, the filtered data can be expressed as linear sums of the original data, multiplied by coefficients. However, one of the problems with linear methods is that there are no restrictions to physically meaningless solutions. In many cases it may be known, for example, that negative signals are meaningless. It may be useful to include these in the algorithm, meaning that linear methods are no longer adequate.

Maximum entropy is probably the most well-known nonlinear method. Consider tossing two unbiased coins. What is the most likely distribution? Is it two tails, one head and one tail, or two heads? The middle distribution is twice as likely and is said to have twice the degeneracy of the other distributions. The problem of the toss of two coins is one in which there are two states (heads and tails) and three levels (0, 1, or 2 coins in each state). The number of coins expected in each of the three levels can be converted to a probability, so the probability of level 0 is 0.25, level 1 is 0.5, and level 2 is 0.25.

A spectrum can also be considered a probability distribution with  $I$  states where each represents a

sampling point (e.g., wavenumber) and an infinite number of levels (subject to a sufficiently high analog to digital conversion). It can be shown that for a sufficiently large number of states relative degeneracy is proportional to entropy, defined by

$$S = - \sum_{i=1}^I p_i \log(p_i)$$

where  $p_i$  is the probability of absorption at point  $i$  in the spectrum. In many cases the probability is defined as the spectral intensity at a given point divided by the sum of all other intensities in the spectrum. Note that entropy requires positive values. For any possible spectrum, the greater the entropy the more likely the spectrum. In the absence of other information, a flat spectrum is one with maximum entropy.

Maximum entropy deconvolution, however, is normally iteratively combined with other methods. For example, least squares curve fitting attempts to create structure in a spectrum. Maximum entropy picks solutions with least structure: the reason is that in the absence of external evidence, there is no reason to assume structure in the reconstructed spectrum: the 'flat map' is the most likely answer. Most algorithms try to decrease mean square errors iteratively. A target residual is selected, according to the desired speed of computational convergence, and the solution with maximum entropy is chosen. Then, the residual is decreased and, again, a maximum entropy solution is found, until convergence.

Maximum entropy has been applied to a large number of techniques such as NMR, Raman, and MS. The method can be very powerful, but on the whole is best suited when there is poor knowledge of the data, or the dataset is somewhat incomplete, e.g., noisy data. If a large amount of information is already known, such as exact lineshapes and there are high signal-to-noise ratios, other more targeted methods are probably more effective.

There are several other nonlinear methods applied in different spectroscopies, the book edited by Jansson provides a broad review of nonlinear deconvolution.

### Multivariate Methods

There has been especially large growth in methods for multiway resolution over the past decade. These relate to signals where there are two or more dimensions, such as in the study of pH equilibria by optical spectroscopy, where one dimension relates to pH and the other wavelength, or diode array high-performance liquid chromatography (HPLC) where

one dimension relates to elution time and the other wavelength. Normally, one dimension (e.g., pH or elution time) is studied in sequence and the aim is to determine the profiles of individual chemical species as a function of this dimension together with their spectral characteristics.

### Principal Component and Factor Analysis

Consider the case of coupled chromatography, such as HPLC–DAD. For a simple chromatogram, the underlying dataset is the sum of responses for each significant compound in the data, which are characterized by (1) an elution profile and (2) a spectrum. This is often written in matrix terms as

$$X = C \cdot S + E$$

where  $X$  is the original data matrix or coupled chromatogram,  $C$  is a matrix consisting of the elution profiles of each compound,  $S$  is a matrix consisting of the spectra of each compound, and  $E$  is an error matrix. An important aim may be to predict  $C$  and  $S$  from  $X$ , allowing the resolution of the original multivariate data matrix into each constituent. Ideally, the predicted spectra and chromatographic elution profiles are close to the true ones, but it is important to realize that we can never directly or perfectly observe the underlying data. There will always be measurement error even in practical spectroscopy. Chromatographic peaks may be partially overlapping or even embedded, meaning that chemometric methods will help resolve the chromatogram into individual components.

One aim of chemometrics is to obtain these predictions after first treating the chromatogram as a multivariate data matrix, and then performing principal component analysis (PCA). Each compound in the mixture is a ‘chemical’ factor with its associated spectra and elution profile, which can be related to principal components, or ‘abstract’ factors, by a mathematical transformation.

PCA results in an abstract mathematical transformation of the original data matrix, which takes the form

$$X = T \cdot P + E$$

where  $T$  represents the scores, and has as many rows as the original data matrix,  $P$  the loadings and have as many columns as the original data matrix, and the number of columns in the matrix  $T$  equals the number of rows in the matrix  $P$ . It is possible to calculate scores and loadings matrices as large as desired, provided the ‘common’ dimension is no larger than the smallest dimension of the original data matrix, and corresponds to the number of

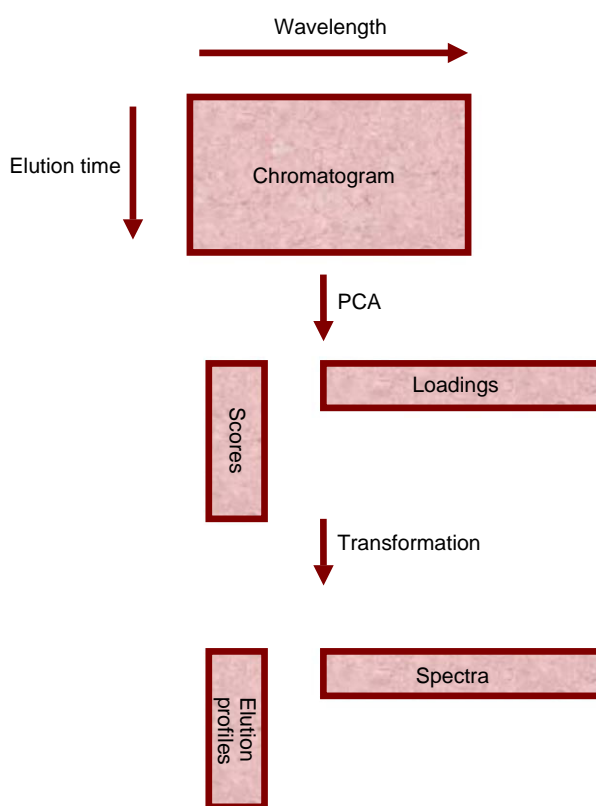

Figure 6 Difference between PCA and factor analysis.

principal components that are calculated. However, ideally the number of columns in  $P$  equals the number of significant components or compounds in the chromatogram.

Principal components regression relates these abstract factors to chemically meaningful factors by finding a matrix  $R$  to give

$$X = C \cdot S + E = T \cdot R \cdot R^{-1} \cdot P + E$$

This procedure is called transformation, rotation, or factor analysis depending on the author and is illustrated in Figure 6. The majority of methods for multivariate resolution differ in how  $R$  is determined.

### Target Factor Analysis

Target factor analysis (TFA) tries to see how closely the predicted pure data relate to targets, for example, a library of known spectra. Can we find a transformation matrix so that the predicted spectra fit closely to known spectra (the targets)? Another popular method is iterative transform factor analysis where the targets are defined iteratively. For example, the original targets may be guesses of the pure component spectra obtained by choosing regions of the data that are expected to most represent pure

components. This model is refined iteratively until a good fit is obtained.

### Eigenvalue-Based Window Methods

A separate group of methods involve calculating the eigenvalues of a multivariate matrix within a window. Each principal component has a size, which is often given by an eigenvalue; the larger, the more it is significant. So if a section of a multiway dataset is subjected to PCA, and there are three compounds in this section, there are likely to be three significant eigenvalues. The size of the eigenvalues can be calculated as the window is changed in size or position.

There are two main alternatives, using a fixed sized window, which is moved along the data, or using an expanding window. For the fixed sized window, the number of significant eigenvalues increases and decreases according to the number of components in the data, whereas for the expanding window it will always increase as the window evolves. In the latter case it is normal to calculate eigenvalues for both forward and backward windows, the latter starting at the end of the data. The two types of method are illustrated in **Figure 7**. The resultant eigenvalues are generally plotted on a logarithmic scale against time.

The result is used to determine regions of maximum purity. These approximate to the elution profiles or spectra (in coupled chromatography) of each component in a mixture that can then be employed in factor analysis as some information on each pure component is known. Sometimes there are embedded peaks, for which there is no pure (or selective or composition 1) region. The eigenvalue plots can still provide valuable information as to where each component elutes but sometimes it is hard to obtain unique mathematical solutions to the determination of information on each compound.

However, using constraints such as non-negativity and unimodality can help.

### Purity-Based Approaches

A separate set of approaches relates to determine selective or pure variables. These are variables that most characterize each individual component in a mixture. For example, in the GC-MS of mixtures there is likely to be a specific  $m/z$  value most characteristic of each component. In HPLC-DAD, we look for selective elution times for each compound.

There are a variety of named approaches such as SIMPLISMA and the Orthogonal Projection Approach. In addition, it is possible to determine derivatives between successive scaled spectra, regions of high purity will result in low values, and so minima in the scaled derivatives can be employed to pinpoint pure regions. Correlation coefficients are another effective alternative, the higher the correlation between two successive spectra in a chromatogram, the more likely two successive points correspond to the same spectrum and so correspond to one pure compound. In regions of coelution, the derivatives will be high and the correlation coefficient low, because the nature of the spectrum will be changing.

Once pure variables have been determined, then it is possible to perform factor analysis as described above, using these pure values either as guesses of spectra (e.g., selective regions of a chromatogram) that can be used to determine elution profiles in overlapping regions, or as guesses of profiles (e.g.,  $m/z$  values of characteristic ions in LC-MS) that can be used to determine spectra of each component. Sometimes constraints such as non-negativity are included in the calculations.

## CHIROPTICAL ANALYSIS

**H-G Kuball**, University of Kaiserslautern, Kaiserslautern, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

‘Chiroptical analysis’ is the application of chiroptical spectroscopy – including absorption, emission, and optical refraction measurements – in order to obtain information about chiral molecules and phases. Lord Kelvin has defined chiral objects in his famous ‘Baltimore Lectures 1889’ by: “I call any geometrical figure or group of points ‘chiral’, and say it has ‘chirality’, if its image in a plane mirror, ideally realized, cannot be brought – by rotation and translation of the geometrical figure or the group of points – into coincidence with itself.” Examples include molecules and chiral anisotropic phases with their long-range orientational and long-range positional order (for a classification by a length scale, four levels of chirality can be introduced. First level: atoms (weak interaction); second level: molecules (geometry); third level: suprastructural chirality (long-range orientational and positional order of atoms/molecules); fourth level: macroscopic objects like helical pillars, staircases, etc.) without symmetry of second kind, i.e., no rotation–reflection symmetry (rotation–reflection axes  $S_n$ ,  $n = 1, 2, \dots$ ). These chiral objects do exist always in two different forms, one being the mirror image of the other (enantiomers and enantiomorphous solids). The introduction of a reference system, like that of Cahn, Ingold, and Prelog (CIP), allows dividing the world of chiral molecules into two classes, the ‘S or R (M or P) world’. For chiral anisotropic phases no universally valid reference systems exist. Exceptions are the left (M) or right

(P) handed helical long-range orientational order of cholesteric and smectic  $C^*$  phase and the left (M) or right (P) handed screw axes of crystals.

In the last decades chiroptical spectroscopy has been mostly applied to chiral ‘isotropic solutions’, the so-called ‘dissymmetric solutions’. Nowadays, chiroptical spectroscopy has been proven to be a prospective tool to analyze chiral anisotropic phases. Here, chirality measurements yield information about the anisotropy of chiral properties of molecules and the chiral long-range positional and orientational order of phases. Especially, the differences of optical constants will be measured possessing for two enantiomers or enantiomorphous phases the same absolute value but opposite signs due to their chirality. Because of these differences in optical constants, light can only propagate in a chiral sample with chiral eigenstates of polarization, i.e., as two orthogonal elliptically or circularly polarized light beams. These eigenstates, determined by the symmetry of the sample (Table 1), penetrate the material without changing their states of polarization. Their existence can be proven by the splitting of unpolarized light penetrating a wedge-shaped sample (Figure 1).

Chiroptical spectroscopy, for which only the circular and elliptical eigenstates are of interest, is usually performed in experimental arrangements with two light beams propagating parallel to each other. They superpose after leaving the sample (Figure 2) to an elliptically polarized light that differs in intensity and polarization from that of the incident light. In a dissymmetric solution with its two refractive indices  $n_L$  and  $n_R$  (Figure 2), the plane of polarization of an incident linearly polarized light is rotated with an angle  $\varphi$  (optical rotation):

$$\varphi = \pi \tilde{v} d (n_L - n_R) \quad (\text{rad}) \quad [1]$$

### Introduction

‘Chiroptical analysis’ is the application of chiroptical spectroscopy – including absorption, emission, and optical refraction measurements – in order to obtain information about chiral molecules and phases. Lord Kelvin has defined chiral objects in his famous ‘Baltimore Lectures 1889’ by: “I call any geometrical figure or group of points ‘chiral’, and say it has ‘chirality’, if its image in a plane mirror, ideally realized, cannot be brought – by rotation and translation of the geometrical figure or the group of points – into coincidence with itself.” Examples include molecules and chiral anisotropic phases with their long-range orientational and long-range positional order (for a classification by a length scale, four levels of chirality can be introduced. First level: atoms (weak interaction); second level: molecules (geometry); third level: suprastructural chirality (long-range orientational and positional order of atoms/molecules); fourth level: macroscopic objects like helical pillars, staircases, etc.) without symmetry of second kind, i.e., no rotation–reflection symmetry (rotation–reflection axes  $S_n$ ,  $n = 1, 2, \dots$ ). These chiral objects do exist always in two different forms, one being the mirror image of the other (enantiomers and enantiomorphous solids). The introduction of a reference system, like that of Cahn, Ingold, and Prelog (CIP), allows dividing the world of chiral molecules into two classes, the ‘S or R (M or P) world’. For chiral anisotropic phases no universally valid reference systems exist. Exceptions are the left (M) or right

(P) handed helical long-range orientational order of cholesteric and smectic C\* phase and the left (M) or right (P) handed screw axes of crystals.

In the last decades chiroptical spectroscopy has been mostly applied to chiral ‘isotropic solutions’, the so-called ‘dissymmetric solutions’. Nowadays, chiroptical spectroscopy has been proven to be a prospective tool to analyze chiral anisotropic phases. Here, chirality measurements yield information about the anisotropy of chiral properties of molecules and the chiral long-range positional and orientational order of phases. Especially, the differences of optical constants will be measured possessing for two enantiomers or enantiomorphous phases the same absolute value but opposite signs due to their chirality. Because of these differences in optical constants, light can only propagate in a chiral sample with chiral eigenstates of polarization, i.e., as two orthogonal elliptically or circularly polarized light beams. These eigenstates, determined by the symmetry of the sample (Table 1), penetrate the material without changing their states of polarization. Their existence can be proven by the splitting of unpolarized light penetrating a wedge-shaped sample (Figure 1).

Chiroptical spectroscopy, for which only the circular and elliptical eigenstates are of interest, is usually performed in experimental arrangements with two light beams propagating parallel to each other. They superpose after leaving the sample (Figure 2) to an elliptically polarized light that differs in intensity and polarization from that of the incident light. In a dissymmetric solution with its two refractive indices  $n_L$  and  $n_R$  (Figure 2), the plane of polarization of an incident linearly polarized light is rotated with an angle  $\varphi$  (optical rotation):

$$\varphi = \pi \tilde{v} d (n_L - n_R) \quad (\text{rad}) \quad [1]$$

**Table 1** Eigenstates of light

<i>Achiral isotropic material</i>	<i>All states of polarization</i>
Chiral isotropic material (dissymmetric material)	Left and right circularly polarized light
Achiral anisotropic material	Parallely and perpendicularly <sup>a</sup> linear polarized light <sup>b</sup>
Chiral anisotropic material	Left and right elliptically polarized light

<sup>a</sup>With respect to the optical axis/axes of the material.

<sup>b</sup>The 'plane of polarization' is defined by the plane built up by the electric field vector and the propagation direction of light.

**Figure 1** Splitting of an unpolarized light beam  $P_0$  by a dissymmetric solution in a wedge-shaped cell or a wedge-shaped chiral anisotropic solid into the two orthogonal eigenstates  $P_1$  and  $P_2$ .  $\chi \neq 0$  except in the case of isotropic material where all states of polarized light, including the unpolarized light, can propagate ( $P_0 = P_1 = P_2$ ).

where  $d$  is the path length of the sample in centimeters,  $\bar{\nu} = 1/\lambda$  the wavenumber of the incident light, and  $\lambda$  the wavelength in centimeters. The specific rotation  $[\alpha]$  for a gaseous, a fluid, or a solid compound is then defined by:

$$[\alpha] = \frac{\alpha}{\rho l} = \frac{\alpha}{ql} \left[ \frac{\text{deg cm}^3}{\text{mol dm}} \right] \quad [2]$$

where  $\rho$  is the density of a pure compound in grams per centimeter cube and  $q$  is the concentration of a dissolved compound in grams per (100 cm<sup>3</sup> solution).  $\alpha$  is given in degree and  $l$  is the length of the cell in decimeters. The molar rotation  $[M]$  can be expressed by

$$[M] = \frac{[\alpha]M}{100} = \frac{100\alpha}{cd} \left[ \frac{\text{deg cm}^3}{\text{mol dm}} \right] \quad [3]$$

where  $M$  is the molecular mass,  $c$  the concentration in moles per liter, and  $d$  the path length in centimeters. Here, one has to have in mind that the conversion of units is made under the condition that  $[M]$  and  $[\alpha]$  maintains their historical units. No IUPAC regulation for SI units does exist, nowadays.

By the absorption of a dissymmetric solution an incident linearly polarized light changes to an

elliptically polarized light with the ellipticity  $tg\theta$

$$\begin{aligned} tg\theta &= \frac{10^{-\varepsilon_L cd/2} - 10^{-\varepsilon_R cd/2}}{10^{-\varepsilon_L cd/2} + 10^{-\varepsilon_R cd/2}} \cong \theta \\ &= \frac{\ln 10}{4} (\varepsilon_L - \varepsilon_R) cd = 0.5757 \Delta \varepsilon cd \end{aligned} \quad [4]$$

$\varepsilon_L$  and  $\varepsilon_R$  are the molar decadic absorption coefficients of left and right circularly polarized light, respectively.  $\Delta \varepsilon = \varepsilon_L - \varepsilon_R$  (l mol<sup>-1</sup> cm<sup>-1</sup>) is the circular dichroism (CD). Often the molar ellipticity  $[\theta]$

$$[\theta] = \frac{100\theta}{cd} = 3300 \Delta \varepsilon \quad [5]$$

is used instead of  $\Delta \varepsilon$ . Because both eigenstates are independent (Figure 2), the Lambert–Beer law does not hold

$$\begin{aligned} I &= I_0 10^{-\bar{\varepsilon} cd} \cosh \left[ \frac{2.303}{2} (\varepsilon_L - \varepsilon_R) cd \right] \\ &\cong I_0 10^{-\bar{\varepsilon} cd} \end{aligned} \quad [6]$$

In most cases the deviation from the Lambert–Beer law is negligible.  $\bar{\varepsilon}$  is the average absorption coefficient of the sample:

$$\bar{\varepsilon} = \frac{1}{2} (\varepsilon_L + \varepsilon_R) \quad [7]$$

The CD and optical rotatory dispersion (ORD) can be given either as a function of the wavenumber  $\bar{\nu}$  (cm<sup>-1</sup>) or the wavelength  $\lambda$  (nm) (Figure 3). The wavenumber is proportional to the energy  $\bar{\nu} = (1/hc)E$  ( $E$  energy). From the physical point of view the presentation as a function of  $\bar{\nu}$  should be preferred but the  $\lambda$  dependence is often taken for historical reasons because most spectroscopic instruments use a  $\lambda$  scale. Especially, the recognition and the analysis of vibrational progressions of an electronic absorption band is easier to handle in the  $\bar{\nu}$  representation than in the nonlinear  $\lambda$  representation. The ORD curve is of a simple sigmoid form for a symmetric and structureless CD band. This ORD

**Figure 2** Propagation of the two orthogonal circularly polarized eigenstates within a dissymmetric sample and the superposition of both eigenstates after leaving the sample.  $\varphi$  is the optical rotation and  $tg\theta = b/a$  the ellipticity of the light ( $a$  is the long axis,  $b$  is the short axis of the ellipse).  $\varphi$  is positive for a clockwise rotation of the plane of polarization. The elliptically polarized light is left handed for  $tg\theta < 0$  and  $\Delta\varepsilon < 0$  and right handed for  $tg\theta > 0$  and  $\Delta\varepsilon > 0$ . The electric field vector  $E$  of the circularly polarized light is given for selected positions (the four quadrants) within the optical path in planes perpendicular to the propagation direction of the light. The state of polarization of the eigenstates does not change while propagating through the sample whereas the absorption changes their intensity. For the sign convention: the observer is facing the propagation direction of the light.

**Figure 3** Cotton effect (CE): CD (.....), ORD (-----), dissymmetry factor  $g$  (.....) and the UV (—) band. The CE is positive if  $\Delta\varepsilon > 0$ . Then the positive lobe of the sigmoid ORD curve lies on the long-wavelength/smaller wavenumber side of the absorption band.  $\Delta\varepsilon$  and  $[M]$  change signs (mirrored at the abscissa) for the enantiomer (negative CE). The long-wavelength region between  $\sim 525$  and  $600$  nm ( $17\,000$  and  $19\,000\text{ cm}^{-1}$ ) is a 'plain positive rotation' or 'normal rotatory dispersion'. The sigmoidal form below  $525$  nm is an 'anomalous rotatory dispersion'. The positive maximum of the ORD curve is a so-called 'peak' whereas the negative minimum is a 'trough'.  $[A] = ([M(\lambda_1)] - [M(\lambda_2)]) / 100$  ( $\lambda_1 > \lambda_2$ ) is the amplitude of the rotatory dispersion curve.

curve can be characterized by its amplitude

$$[A] = \frac{[M(\bar{\nu}_1)] - [M(\bar{\nu}_2)]}{100}$$

The amplitude is positive (negative) if  $[A] > 0$  ( $[A] < 0$ ) for  $\bar{\nu}_1 < \bar{\nu}_2 \{ \lambda_1 > \lambda_2 \}$  ( $\bar{\nu}_1 > \bar{\nu}_2 \{ \lambda_1 < \lambda_2 \}$ ). **Figure 3** presents the so-called positive Cotton effect

(CE) where  $\Delta\varepsilon > 0$  and  $[A] > 0$ . For the corresponding enantiomer the negative CE will be obtained:  $\Delta\varepsilon < 0$  and  $[A] < 0$ .

CD and ORD are correlated by Kramers–Kronig transformations

$$\varphi(\omega) = \frac{2}{\pi} \oint \frac{\omega \theta(\bar{\omega})}{\bar{\omega}^2 - \omega^2} d\bar{\omega} \quad [9]$$

and

$$\theta(\omega) = -\frac{2}{\pi} \oint \frac{\bar{\omega} \varphi(\bar{\omega})}{\bar{\omega}^2 - \omega^2} d\bar{\omega}. \quad [10]$$

$\omega = 2\pi\nu = 2\pi\bar{\nu}c$  with  $\nu$  the frequency and  $c$  the vacuum velocity of light. The Kramers–Kronig transforms can be used to check an experimental result in critical situations and assure ORD measurements by CD measurements and vice versa by calculating the ORD from the CD and vice versa by eqns [9] and [10].

## Theory

For molecules the ‘optical chirality measurements CD and ORD’ can be performed between vacuum ultraviolet (UV) (ECD: CD of electronic transitions) and infrared (IR) (VCD: CD of vibrational transitions) spectral regions in which  $\lambda$  is large in comparison with the diameter of a molecule. Suprastructural chirality can be observed in a spectral region in which  $\lambda$  is in the order of the periodicity of the chiral structures as can be established by the ‘selective reflection’ of a cholesteric phase in the IR spectral region.

The simplest approach to understand the interaction of light with chiral molecules is the assumption of a diastereomeric interaction between circularly polarized light and chiral molecules. This leads to different absorption coefficients and refractive indices for left ( $\varepsilon_L$ ,  $n_L$ ) and right ( $\varepsilon_R$ ,  $n_R$ ) handed circularly polarized light with left handed and right handed molecules, respectively. The interaction of light with a molecule can be quantitatively described by the introduction of an electric dipole transition moment  $\langle \underline{\mu} \rangle_{ga}$  and a magnetic dipole transition moment  $\langle \underline{m} \rangle_{ag}$ . The scalar products of these vectors  $\langle \underline{\mu} \rangle_{ga}$  and  $\langle \underline{m} \rangle_{ag}$  (eqns [13] and [17]) are proportional to the probability by which the molecule in the state ‘g’, characterized by the wavefunction  $\psi_g$  and the energy  $E_g$ , is excited to the state ‘a’, given by the wavefunction  $\psi_a$  with the energy  $E_a$ :

$$\langle \underline{\mu} \rangle_{ga} = \langle \psi_g | \underline{\mu} | \psi_a \rangle \quad [11]$$

$$\langle \underline{m} \rangle_{ag} = \langle \psi_a | \underline{m} | \psi_g \rangle \quad [12]$$

**Figure 4** Intensity of absorption as a function of the angle between the electric field of the light and the electric dipole transition moment direction  $\langle \underline{\mu} \rangle_{ga}$ :  $\varepsilon(\alpha) = \langle \underline{\mu} \rangle_{ga}^2 \cos^2 \alpha$ .

where  $\underline{\mu}$  [Debye] and  $\underline{m}$  [BM] are the electric and magnetic dipole operators, respectively. The directions of the vectors  $\langle \underline{\mu} \rangle_{ga}$  and  $\text{Im} \{ \langle \underline{m} \rangle_{ag} \}$  determine the directions along which the light has to be polarized in order to have the maximum of absorption ( $\alpha = 0^\circ$  and  $180^\circ$  in **Figure 4**). The magnetic dipole transition moment is a complex quantity. Thus,  $\text{Im} \{ \}$  means the imaginary part of  $\langle \underline{m} \rangle_{ag}$ . Light that is polarized perpendicular to  $\langle \underline{\mu} \rangle_{ga}$  and  $\text{Im} \{ \langle \underline{m} \rangle_{ag} \}$ , respectively, penetrates the sample without being absorbed ( $\alpha = 90^\circ$  and  $270^\circ$  in **Figure 4**).

For a transition between the vibronic ground state  $g \equiv |Nn\rangle$  and the excited state  $a \equiv |Kk\rangle$  follows for the integrated intensity of the absorption:

$$D^{NnKk} = \langle \underline{\mu} \rangle_{NnKk}^2 + \langle \underline{m} \rangle_{KkNn}^2 \cong \langle \underline{\mu} \rangle_{NnKk}^2 \quad [13]$$

$D^{NnKk}$  is the dipole strength of the transition  $|Nn\rangle \rightarrow |Kk\rangle$ .  $N$  and  $K$  characterize the electronic ground and excited state and the quantum numbers  $n$  and  $k$  do correspond to their vibrational states, respectively. The contribution of the magnetic transition in eqn [13] can be neglected because of  $|\langle \underline{\mu} \rangle_{NnKk}|^2 \gg |\langle \underline{m} \rangle_{KkNn}|^2$ . The corresponding integrated intensity of the CD band, the rotational strength, is given by the scalar product

$$\begin{aligned} R^{NnKk} &= \sum_{i=1}^3 \text{Im} \{ \langle \underline{\mu}_i \rangle_{NnKk} \langle \underline{m}_i \rangle_{KkNn} \} \\ &= \text{Im} \{ \langle \underline{\mu} \rangle_{NnKk} \cdot \langle \underline{m} \rangle_{KkNn} \} \\ &= |\langle \underline{\mu} \rangle_{NnKk}| |\langle \underline{m} \rangle_{KkNn}| \cos \vartheta \end{aligned} \quad [14]$$

$\text{Im} \{ \}$  means the imaginary part of the scalar product.  $\vartheta$  is the angle between the transition moments  $\langle \underline{\mu} \rangle_{NnKk}$  and  $\langle \underline{m} \rangle_{KkNn}$ . The quantities  $\langle \underline{\mu}_i \rangle_{NnKk}$  and  $\langle \underline{m}_i \rangle_{KkNn}$  ( $i = 1, 2, 3$ ) are the three components (coordinates) of the electric and magnetic dipole

transition moments with respect to a chosen molecule-fixed coordinate system.

With the line shape  $F^{NnKk}(\bar{\nu})$  of the transition  $|Nn\rangle \rightarrow |Kk\rangle$ , which is equal for most of the experimental conditions for the absorption and the CD bands, the absorption coefficient  $\varepsilon$  is given by

$$\varepsilon(\bar{\nu}) = \frac{B\bar{\nu}}{12} \sum_n \sum_{Kk} D^{NnKk} F^{NnKk}(\bar{\nu}) = \sum_K \varepsilon^{NK}(\bar{\nu}) \quad [15]$$

$$B = \frac{32\pi^3 N_A}{10^3 h c_0 \ln 10} = 7.653 \times 10^{40} \quad \text{cgs} \quad [16]$$

$N_A$  is Avogadro's number,  $c_0$  the velocity of light, and  $h$  is Planck's constant. Summation over all vibrational contributions then leads to the dipole strength of the electronic transition  $|Nn\rangle \rightarrow |Kk\rangle$ :

$$D^{NK} = \langle \underline{\mu} \rangle_{NK}^2 \quad [17]$$

For CD  $\Delta\varepsilon$  follows

$$\Delta\varepsilon(\bar{\nu}) = \frac{B\bar{\nu}}{3} \sum_n \sum_{Kk} R^{NnKk} F^{NnKk}(\bar{\nu}) = \sum_K \Delta\varepsilon^{NK}(\bar{\nu}) \quad [18]$$

Summation over all vibrational contributions leads to the rotational strength of the electronic transition  $|Nn\rangle \rightarrow |Kk\rangle$ . The dipole strength and the rotational strength of an electronic transition can be experimentally determined by integration over the corresponding UV and CD band by

$$D^{NK} = \frac{12}{B} \int_{\text{band}} \frac{\varepsilon^{NK}(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \quad [19]$$

and

$$R^{NK} = \frac{3}{B} \int_{\text{band}} \frac{\Delta\varepsilon^{NK}(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \quad [20]$$

With the Kramers–Kronig transforms (eqn [9]), the frequency dependence of the molar optical rotation (ORD) can be obtained as follows:

$$\begin{aligned} [M(\bar{\nu})] &= \frac{288\pi N_A \bar{\nu}}{3hc} \sum_n \sum_{Kk} R^{NnKk} J_2^{NnKk}(\bar{\nu}) \\ &= \sum_K [M^{NK}(\bar{\nu})] \end{aligned} \quad [21]$$

$$J_2^{NnKk}(\bar{\nu}) = \oint \frac{\bar{\nu}' F^{NnKk}(\bar{\nu}') d\bar{\nu}'}{\bar{\nu}'^2 - \bar{\nu}^2}. \quad [22]$$

$J_2^{NnKk}(\bar{\nu})$  (eqn [22]) is the principal value of the integral over the singularity at the wavenumber of the corresponding excitation ( $\bar{\nu}' = \bar{\nu}$ ). The dispersion

of the well-known Rosenfeld equation for the ORD for  $\lambda \gg \lambda_{NK}$  is obtained from eqn [22] if vibrational states  $n$  and  $k$  do not contribute:

$$J_2^{NK}(\bar{\nu}) = \frac{\bar{\nu}^2}{\bar{\nu}_{NK}^2 - \bar{\nu}^2} = \frac{\lambda_{NK}^2}{\lambda^2 - \lambda_{NK}^2} \quad [23]$$

$\bar{\nu}_{NK}$  and  $\lambda_{NK}$  are the spectral positions of the corresponding transition.

To every absorption band  $\varepsilon^{NK}(\bar{\nu})$  belongs a CD band  $\Delta\varepsilon^{NK}(\bar{\nu})$  and a corresponding ORD curve  $[M^{NK}(\bar{\nu})]$  (Figure 3). The right-hand side of eqns [18] and [21] are the sum over contributions of all electronic transitions. Thus, the CD and ORD spectra can be interpreted as a sum of Cotton effects. It is evident from Figures 3 and 5 that the ORD curve possesses a larger half-bandwidth than  $\Delta\varepsilon^{NK}(\bar{\nu})$ . As a consequence the molar optical rotation  $[M(\bar{\nu})]$  is, even in spectral regions far away from absorption bands, always a sum of contributions of many transitions. The experimental CD bands in a given wavelength region are often determined by only one or at least by a few transitions.

Completely unstructured CD and UV bands are the exception, not the rule. With any electronic excitation a large number of rotational and vibrational states are involved in the absorption process. Neglecting rotational states, because they do not appear in normally measured CD spectra, every vibronic electronic state  $|Nn\rangle$  or  $|Kk\rangle$  can be described within the Born–Oppenheimer approximation by the product of vibrational states  $n(N)$  and  $k(K)$  and the electronic states  $N$  and  $K$ , respectively. Often, formally forbidden – mostly weak – absorption bands gain their

**Figure 5** CD, ORD, and UV spectra as a sum of contributions of different transitions, i.e., different chromophores  $|N\rangle \rightarrow |K\rangle$ .  $\bar{\nu}$  is a wavenumber in the region of a 'normal rotatory dispersion' and  $\bar{\nu}$  is a wavenumber at the center of a CE.

**Figure 6** Vibrational progressions contribute to a CD spectrum of an electronic transition either with equal (A) or different (B) sign. For (A) the CD and UV bands are quite similar whereas for (B) the CD band possesses a larger vibrational structure than the absorption band (pseudovibrational structure) because of the superposition of CD curves of different signs.

intensity by vibronic coupling with intensive allowed transitions via totally symmetric ( $\bar{\nu}_1$ ) and nontotally symmetric ( $\bar{\nu}_X$ ) vibrations (intensity borrowing). Then, these vibrations contribute via vibrational progressions (eqns [24] and [25]) to the CE with equal or different sign (Figure 6).

$$\bar{\nu} = \bar{\nu}_{00} + n\bar{\nu}_1 \quad [24]$$

$$\bar{\nu} = \bar{\nu}_{00} + \bar{\nu}_X + n\bar{\nu}_1 \quad [25]$$

$n = 1, 2, 3, \dots$  and  $\bar{\nu}_{00}$  is the wavenumber of the 0–0 transition, i.e., the vibrational free electronic transition.

Absorption bands can be classified by the symmetry of the involved vibrational and electronic states. This symmetry determines also the transition moment directions, i.e., the orientation of the transition moment vector  $\langle \mu \rangle_{NnKk}$  within the molecule. On the other hand, an experimentally determined transition moment direction allows assigning an absorption band. The transition moment directions can be evaluated from the linear dichroism described in polarized spectroscopy in terms of the degree of anisotropy  $R$ , given here for a uniaxial phase:

$$R = \frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + 2\varepsilon_2} = \frac{\varepsilon_1 - \varepsilon_2}{3\varepsilon} \quad [26]$$

$\varepsilon_1$  and  $\varepsilon_2$  are the absorption coefficients for linear polarized light polarized parallel or perpendicular to the optical axis of the uniaxial phase. The following

equations hold:

$$\varepsilon_1 = \varepsilon + (\varepsilon_{33}^* - \varepsilon)S^* + \frac{1}{\sqrt{3}}(\varepsilon_{11}^* - \varepsilon_{22}^*)D^* \quad [27]$$

with

$$\varepsilon = \frac{1}{3}(\varepsilon_1 + 2\varepsilon_2). \quad [28]$$

$S^*$  and  $D^*$  are the Saupe order parameters that describe the order of the molecules in the absorbing sample.  $\varepsilon_{ii}^*$  ( $i = 1, 2, 3$ ) are the diagonal elements of the transition moment tensor. They are proportional to the squares of the components of the transition moments ( $\langle \mu_i^* \rangle$  ( $i = 1, 2, 3$ )) given with respect to a molecule fixed-coordinate system ( $x_i^*$ ):  $\varepsilon_{ii}^* \propto (\langle \mu_i^* \rangle)^2$  (see section on Circular dichroism of chiral anisotropic phases without suprastructural chirality).

A further classification of the CE of a band is obtained with the dissymmetry factor as a function of wavenumbers by

$$g(\bar{\nu}) = \frac{\Delta\varepsilon^{NK}(\bar{\nu})}{\varepsilon^{NK}(\bar{\nu})} \quad [29]$$

or for the electronic transition  $|N\rangle \rightarrow |K\rangle$  by

$$g = \frac{4R^{NK}}{D^{NK}} \quad [30]$$

The size of  $g$  also indicates whether the CD of an absorption band is measurable or not.

## Chiroptical Methods

### Methods, Techniques, and Problems

ECD, VCD, Raman optical activity (ROA), and ORD are at disposal in a spectral range between the IR and the vacuum UV. ACD and AORD, the CD and ORD of chiral anisotropic phases are only available in the UV/vis spectral range. The specific rotation, as a standard, is measured with the sodium D-line. For special applications other lines, e.g., mercury lines, have been taken. Indirect methods for chiroptical analyses are the nuclear magnetic resonance (NMR) spectroscopy of diastereomeric compounds and the chiral induction of cholesteric phases (helical twisting power (HTP)) combined with ACD/CD and the corresponding selective reflection.

There are three main fields for chiroptical analyses:

#### (A) Structural information

1. the absolute configuration,
2. the structure and diversity of conformations,
3. the characterization of compounds,
4. the recognition of time dependent structural variation

- (B) Analytical measurements
5. the concentrations of chiral compounds, e.g., saccharose (saccharimetry)
  6. the enantiomeric excess via optical purity
  7. the enantiomeric separation during a chromatographic run in liquid chromatography
- (C) Phase properties
8. pretransitional order near a phase transition
  9. the suprastructural chirality in crystals, films, membranes, and liquid crystal phases.

All techniques have been more or less successfully applied to solve problems in different scientific fields. Table 2 gives a survey of the available techniques and their main field of application.

### CD Contra ORD

In principle, CD and ORD yield identical information because they are Kramers–Kronig transforms (eqns [9] and [10]). Thus, it seems to be sufficient to measure either CD or ORD. This is only true from the theoretical point of view because of some practical reasons:

1. CD and ORD can only be measured in confined parts of the spectrum.
2. It is more convenient to analyze CD than ORD spectra because of its smaller bandwidth. The large bandwidth of  $[M^{NK}(\bar{\nu})]$  leads to a large background effect in the spectral region of all other chromophores. This background effect is difficult to correct.
3. The half-bandwidth of an absorption band ( $\epsilon^{NK}(\bar{\nu})$ ) and the corresponding CD band ( $\Delta\epsilon^{NK}(\bar{\nu})$ ) is approximately the same. This allows an easier assignment of the CD band to the corresponding absorption band.
4. The analysis of vibrational progressions can be easier performed with CD than ORD because vibrational progressions often contribute with bands

of different signs to CD and thus an ‘apparent’ vibrational structure of the CD band is obtained in contrast to the less structured band shape of the absorption band. The vibrational structure of an ORD curve is very complex and nearly not separable into contributions of different vibrational progressions.

5. The ECD spectra can be theoretically calculated with sufficient accuracy for a direct comparison of a calculated and an experimental spectrum.

6. Last but not least, the calculation of an ORD spectrum from the CD spectrum with the Kramers–Kronig relation (eqn [9]) is easier to perform than the calculation of the CD spectrum from the ORD curve.

The very first systematic chiroptical analyses have been obtained with ORD measurements in the 1950s and 1960s. The dominance of the ORD analyses has been broken by commercial CD instruments in the 1960s when CD and ORD were measurable with an equivalent accuracy. Since that time ORD is just of interest for selected problems. It should be mentioned here that a new development based on the invention of new numerical quantum mechanical methods, which allows calculating  $[\alpha]_D^T$  with a sufficient accuracy, may lead to a situation in which even CD, VCD, and ORD measurements can be avoided. Here, in order to avoid experimental artifacts by association, etc.,  $[\alpha]_D^T$  has to be extrapolated with  $c \rightarrow 0$ :  $[\alpha]_{D,c \rightarrow 0}^T$  (see section on Quantum mechanical computation for electronic circular dichroism and vibrational optical activity).

ORD measurements in the IR region never have played any role. The ORD method has to be applied in the UV/vis spectral region if a compound does not possess a suitable chromophore. But in order to avoid an ORD analysis, ‘chromophore-free compounds’ will often be substituted with suitable absorbing groups (see section on Electronic circular dichroism for compounds without a chromophore).

### The Chromophore as a Probe for Chirality – Assignment of Transitions

The concept of the ‘chromophore’ is of eminent importance for probing chiral structures of molecules and their surroundings. But what is a chromophore? In chemical textbooks, a chromophore is a molecule or a group in a molecule that is the ‘carrier of color’ in the visible spectral region. More generally, one chromophore does belong to every absorption band and vice versa. But besides this, the notion is only intuitively defined. From the spectroscopic point of view a chromophore can be defined as an area of a molecule in which some properties have changed after the molecule became excited. In this context measurable and computable properties are the

**Table 2** The main applications of chiroptical methods

Numbering given in the list above	Technique/method						
	ECD	VCE	ROA	ORD	$[\alpha]$	ACD	HTP
A-1	+	+	+		∇	+	∇
A-2	+	+	+	∇

C-9	+					∇	+

+, main application; ∇, possible application.

geometry, charge distribution, polarizability, etc. From a chemist's view a chromophore can be identified by, e.g., a substitution of an auxiliary group that leads to a large or at least a distinct change of the absorption if the area around the position of the substitution belongs to the chromophore. In most cases a chromophore is located in a small restricted part of a molecule, bound to functional groups. Sometimes the whole molecule can be a chromophore as, e.g., with naphthalene with its  $\pi\pi^*$  transitions. The geometrical areas of different chromophores do often overlap, especially those that belong to absorption bands in very different spectral regions. A new chromophore comes into being if the excitation energy of, e.g., two chromophores, is of similar size, a phenomenon well known from the exciton coupling. The location of a chromophore in a molecule is of importance for the applicability of sector and helicity rules for adjacent chromophores. Adjacent chromophores should possess similar or even identical rules and, by this, should give similar or identical results about the surroundings of the chromophore.

In the context discussed above, 'characterizing a chromophore' means an assignment of the absorption band to its corresponding quantum mechanical states. The electric transition moment direction of the absorption band belonging to the chromophore that can be experimentally determined from the degree of anisotropy  $R$  (eqn [26]) is an important information for an unequivocal assignment. Furthermore, the dissymmetry factor  $g$  (eqn [30]) rewritten by eqns [14] and [17] into

$$g = \frac{4|\langle m \rangle_{NK}|\cos \vartheta}{|\langle \underline{\mu} \rangle_{KN}|} \quad [31]$$

allows to identify four types of chromophores. Three types of chromophores possess a local symmetry and so are called inherent symmetric. Their chirality effects are induced through a perturbation by atoms or groups in their surroundings. This leads to transitions that are:

1. magnetically allowed and electrically forbidden;
2. magnetically forbidden and electrically allowed; and
3. magnetically and electrically forbidden.

Dipole transitions magnetically allowed and electrically forbidden are, e.g., the  $n\pi^*$  transitions of the carbonyl group in aldehydes or ketones or the d-d transition of transition metal complexes. For an allowed magnetic dipole transition,  $|\langle m^{NK} \rangle|$  is  $\sim 10^{-21}$  (cgs). For a forbidden electric dipole

transition,  $|\langle \mu^{NK} \rangle|$  is  $\sim 10^{-19}$  to  $10^{-20}$  ( $\epsilon \sim 10$ – $100$ ). Thus,  $g$  is  $\sim 10^{-2}$  to  $10^{-1}$  and the CD is easily measurable. The absorption of the  $n\pi^*$  transitions often gains intensity from the effect of vibronic coupling with allowed  $\pi\pi^*$  transitions via nonsymmetric vibrations induced by the perturbation of the symmetry of the chromophore by its surroundings. For an electrically allowed and magnetically forbidden dipole transition,  $g$  is  $\sim 10^{-3}$  to  $10^{-6}$  and thus its corresponding CD is difficult to measure because of its strong absorption ( $\epsilon$  between  $10^4$  and  $10^6$ ) as found, e.g., for  $\pi\pi^*$  and  $\sigma\sigma^*$  transitions. For the third type of chromophore no common rule can be given. They are often transitions between  $\pi$  and  $\sigma^*$  or  $\sigma$  and  $\pi^*$  orbitals.

The fourth, the so-called inherent dissymmetric chromophore, does not possess local symmetry. Therefore, the transitions belonging to these chromophores are magnetically and electrically allowed. Inherent dissymmetric chromophores are often found with so-called 'form chiral' molecules for which atropisomers like binaphthols are typical representatives. Further examples are chromophores that come into being by exciton coupling. In both cases the dissymmetry factor  $g$  is in the order of  $10^{-2}$  to  $10^{-1}$  and the CD is easily measurable in spite of the fact that the absorption coefficients of these compounds are often very high ( $\epsilon$  between  $10^4$  and  $10^6$ ).

## Absolute Configuration – Stereochemical Application

In spite of the fact that nowadays well established and widely applicable X-ray techniques to determine the absolute configuration are available, these methods cannot displace chiroptical analyses, not only because the X-ray analyses needs good crystalline material. With ECD, VCD, and ROA, besides configurational chirality the conformational chirality of the diverse conformations of nonrigid molecules can also be analyzed.

## Experimental Information

**Electronic and vibrational circular dichroism spectroscopy** With commercially available instruments the accessible spectral region of ECD and VCD spectroscopies lies nowadays between  $\sim 800$  ( $1.25 \mu\text{m}$ ) and  $62\,500 \text{ cm}^{-1}$  ( $160 \text{ nm}$ ). From the spectroscopic point of view the chosen solvents should be free of absorption and in order to have only a small solvent/solute interaction they should be as nonpolar as possible. Acyclic or cyclic hydrocarbons are a good choice for the UV/vis absorption region if sufficient solubility is guaranteed. As a compromise, dioxane,

methanol, and acetonitrile are often used for the UV/vis spectral region. For the IR region besides neat liquids any IR solvent can be used, especially H<sub>2</sub>O, D<sub>2</sub>O, DMSO-d<sub>6</sub>, etc. Measurements in the gaseous state are difficult to perform because the low density of the gas requires long path lengths – often in the order of 100 cm and more. The concentration range for the CD in the UV/vis region has to be chosen between  $\sim 10^{-5}$  and  $10^{-1}$  mol l<sup>-1</sup>, depending on the type of chromophore and the optical quality of the CD instruments. For the IR measurements the concentration is in the range of  $\sim 0.01$  and  $0.6$  mol l<sup>-1</sup> and path length lies between 5  $\mu$ m and 1 cm.

**Fluorescence detected circular dichroism** Often  $\Delta\epsilon$  of a compound is too small or the amount of available material is not sufficient to perform a CD or ORD measurement. The fluorescence detected circular dichroism (FDCD) allows improving the sensitivity and selectivity of the analysis by observing the difference of the fluorescence intensities of molecules excited with left ( $I_L$ ) and right ( $I_R$ ) circularly polarized light. This difference is caused by a different population of the excited states of an enantiomer of a compound when excited with left or right circularly polarized light. Therefore, the information obtained corresponds to the ground state like that measured in absorption. In spite of the fact that FDCD is a long known technique its application was limited because of a poor signal-to-noise ratio and the often existing serious artifacts. For measurements using viscous solvents also the anisotropy induced by photoselection can falsify the result. Recently gained experimental improvements have changed this situation.

**Chiroptical luminescence** Circular polarized luminescence (CPL) allows obtaining information about excited state structures. Corresponding achiral information can be obtained from electrochromic phenomena of molecules. Serious experimental problems, which often lead to more artifacts than acceptable, have prohibited a broad application of this method. Information can be obtained about S $\rightarrow$ T transitions of enones and ketones. For metal complexes kinetic studies about stereochemical dynamics are available. New experimental developments seem necessary for a broad application of the CPL.

### Assignment of the Absolute Configuration

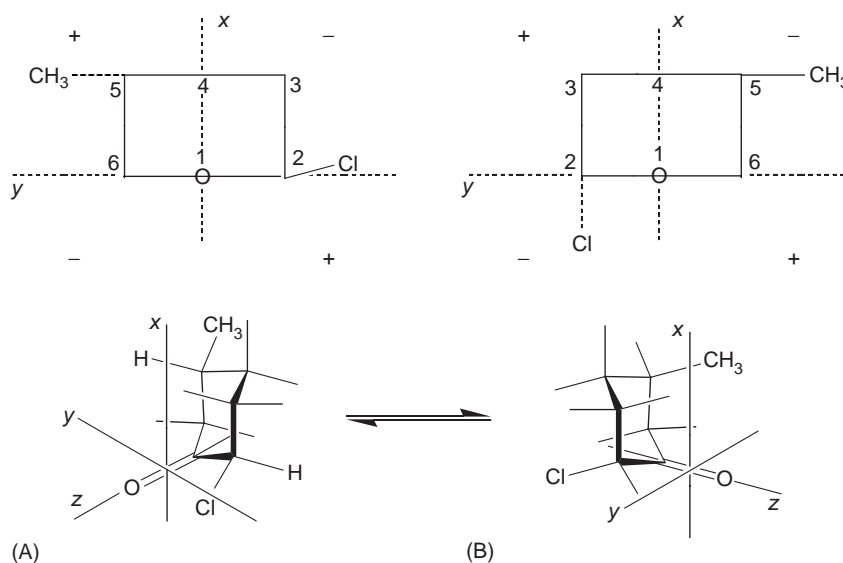

The basis for an assignment of the absolute configuration is the knowledge of the CE, the rotational strength  $R$  (eqn [14]), or the dissymmetry factor  $g$

(eqns [29] and [30]) of one or more absorption bands. In addition, methods are needed that correlate the sign of CE,  $R$ , or  $g$  with the absolute configuration. In principle, there are two different possibilities:

1. The assignment by semiempirical and empirical rules known as sector and helicity rules. Sector rules can be applied to inherent symmetric chromophores. Helicity rules have been deduced for inherent dissymmetric chromophores.
2. The comparison of the computed rotational strength or the corresponding CD spectra with experimentally determined CD spectra.

Whereas sector rules and helicity rules have been very successfully applied for the CD of electronic transitions (ECD), their applicability in VCD spectroscopy is very limited.

**Sector rules for electronic circular dichroism** The first known rule, the octant rule for the  $n\pi^*$  transition of cyclic ketones, can be depicted using the local  $C_{2v}$  symmetry of the carbonyl group: C=O. Their two symmetry planes decompose the space outside the chromophore into four quadrants (Figure 7). The simplest chiral system is obtained by taking the C=O chromophore and one atom positioned out of the symmetry planes in one of the quadrants. Because this simple system is chiral, the atom induces a CE in the  $n\pi^*$  band that is assumed for the following discussion to be of positive sign. The same atom in a mirror image position, i.e., in one of the two neighboring quadrants, leads to the enantiomer of the original system and, thus, the induced CE is of opposite sign. Moving the atom on a circle parallel to the  $x, y$  plane through the four quadrants the sign pattern for the induced CD has to be ‘plus-minus-plus-minus’ because no chiral zero is allowed on the circle except the atom lies in the  $x, z$  or  $y, z$  symmetry plane. Qualitative summation of the effect of all atoms of the molecule in the different quadrants leads to the CE of the  $n\pi^*$  transition. Identical atoms in mirror image position compensate each other. Atoms positioned in the symmetry planes do not contribute to the CE at all. Atoms or groups with a higher polarizability yield a higher contribution except, e.g., in the case of fluorine. Experimental results have shown that a quadrant rule does not hold for the C=O group. An additional plane is needed for a correct sign pattern. This additional plane, which decompose the space into eight octants, has been found to be the nodal plane of the  $\pi^*$  orbital of the carbonyl group. In a modern presentation of the octant rule, instead of the flat nodal plane of the  $\pi^*$  orbital, a curved plane has been introduced. By convention, a

**Figure 7** Octant rule depicted with the equilibrium of diequatorial (A) and diaxial (B) *trans*-2(*R*)-chloro-5(*R*)-methylcyclohexanone and their octant projection diagrams. The cyclohexanone ring lies in the four rear octants. The oxygen of the carbonyl group is directed along the positive *z*-axis (viewing direction is against the positive *z*-axis). The numbers in the octant projection diagrams indicate the position of carbon atoms of the cyclohexanone ring. The chlorine atom in (A) is positioned nearer to the symmetry plane of the carbonyl chromophore ( $\sigma_{yz}$ ). The sign pattern for the CE contributions of atoms is given for the four rear octants.

compound is positioned in the octant as shown in **Figure 7**. The main part of the molecule then lies in the four rear octants. The induced sign of the CD by a perturbing atom in the *x*, *y*, *z* position is then given by the product of its coordinates, i.e.,  $\text{sign}(x \cdot y \cdot z)$  (**Figure 7**). An attempt to quantify the octant rule has failed because of a number of theoretical restrictions of this simple perturbation model. The rule can also be derived from E. Ruch's and A. Schönhofer's theory of chirality functions using only symmetry arguments. Furthermore, the  $n\pi^*$  transition in a  $C_{2v}$  chromophore is a forbidden electric dipole transitions that gains its absorption intensity from vibronic coupling with neighbored  $\pi\pi^*$  transitions. Hereby different vibrational progressions yield contributions of equal or opposite sign to the CD band. The rule fails when the ratio of the CD intensities, belonging to the positive and negative progressions, become interchanged in comparison to the ratio of the reference compounds from which the rule have been derived. There is another problem worthy of mentioning: How large can a perturbation be before the perturbing atom or group has to be included into the originally defined chromophore in order to create a new chromophore. The new chromophore possibly possesses another symmetry or is even converted to an inherently dissymmetric chromophore. In any case, then other sector or helicity rules hold.

For many inherent symmetric chromophores sector rules have been derived. With an increasing

number of symmetry elements for a chromophore the spatial areas in which atoms induce a contribution to the CD of the same sign will get smaller and smaller. Therefore, such rules should be used only with care.

**Helicity rules for electronic circular dichroism** For inherent dissymmetric chromophores all transitions are magnetically and electrically allowed and the dissymmetry factor *g* is, in principle, larger than for inherent symmetric chromophores. Furthermore, the CD is only determined by the geometry of the chromophore without any influence from its surroundings. An unequivocal correlation between a helical sense of a chromophore and the sign of the CE can be given as, e.g., for polymers or biopolymers (e.g., DNA) if atoms or groups in the chromophore can be exactly ordered on a helical line.

For small molecules the selected atoms for defining a helical structure are often only approximately on a helical line. Thus, the helical sense for the following helicity rule of the cisoid enone is uncertain, in principle: The helical sense of the cisoid enone chromophore, e.g., is left handed (right handed) if the CD of the  $n\pi^*$  transition  $\sim 340$  nm is negative (positive). For the  $\pi\pi^*$  transition  $\sim 220$  nm  $\Delta\epsilon > 0$  ( $\Delta\epsilon < 0$ ) for a left handed (right handed) helix. An equivalent rule can be applied to the long-wavelength  $\pi\pi^*$  transition of a diene chromophore. In the given example the positive (negative) helicity is defined by a positive (negative) dihedral angle about the central C–C bond

of the enone chromophore. In this example, the helical sense is only unequivocally defined because the orientation of the helix axis within the molecule, the central C–C bond, is given, i.e., when choosing atoms to approximate a helix, at first a direction for the helix axis has to be chosen because a given helical sense is not unequivocal without the knowledge of orientation of this axis within the molecule. For the twisted diene C=C–C=C, e.g., two different axes with helices of opposite sense can be approximated: one lying parallel to the C<sub>2</sub> symmetry axis, the other parallel to the C–C single bond. One has to be aware of this problem especially when also different atoms have been chosen to define a helical order within a molecule. It is interesting to see that for well chosen axes the sign change of the helix sense can be correlated to a measurable anisotropy of the CD, experimentally found in ACD spectroscopy with, e.g., binaphthols.

The helicity rule of the exciton chirality method is one of the most applied rules for the UV/vis spectral region. This rule possesses a very high reliability for inherent dissymmetric molecules with two identical or similar very strongly absorbing groups. The interaction of two identical chromophores *i* and *j* with their degenerate excited state leads to two non-degenerate states *K*<sub>1</sub> and *K*<sub>2</sub> (Figure 8). The resulting partially overlapping absorption bands  $|N\rangle \rightarrow |K_1\rangle$  and  $|N\rangle \rightarrow |K_2\rangle$  are polarized approximately perpendicular to each other as a consequence of a

**Figure 8** The energy scheme of the exciton chirality method presented for binaphthyl.  $\alpha$  and  $\beta$  indicate the exciton transitions  $|N\rangle \rightarrow |K_1\rangle$  and  $|N\rangle \rightarrow |K_2\rangle$ , respectively.  $2V_{ij}$  is the energy splitting induced by the interaction between both chromophores *i*, *j*. The Newman projections depict the rule for the assignment of the absolute configuration by correlating the sign of the couplet and the dihedral angle.

symmetric and an antisymmetric coupling of the electric dipole transitions in the monomeric units. In the simplest approximation the dipole strength of the absorption of the ‘dimer’ is twice the absorption of the monomer unit. The CD of the new transitions are opposite in sign and their rotational strengths is given by

$$R^{NK_1} = -R^{NK_2} = \underline{R}_{ij}(\langle \underline{\mu} \rangle_{NK_1}^i \cdot \langle \underline{\mu} \rangle_{NK_2}^j) V_{ij} \quad [32]$$

where  $2V_{ij}$  is the Davidov splitting and  $\langle \underline{\mu} \rangle_{NK_1}^i$  and  $\langle \underline{\mu} \rangle_{NK_2}^j$  are the transition moments in the unperturbed monomeric units.  $\underline{R}_{ij}$  is the interchromophoric distance vector between the monomeric units.

Often the energy splitting  $2V_{ij}$  is small. Then the splitting of the absorption bands is also small and the second band only appears as a shoulder whereas in the CD spectrum both bands of opposite sign are easily detected. The superposition of the CD curves of both transitions leads to a sigmoidal CD curve, a couplet, which can be positive ( $\Delta\epsilon(\bar{\nu}_1) > \Delta\epsilon(\bar{\nu}_2)$ ;  $\bar{\nu}_1 < \bar{\nu}_2$ ) or negative ( $\Delta\epsilon(\bar{\nu}_1) < \Delta\epsilon(\bar{\nu}_2)$ ;  $\bar{\nu}_1 < \bar{\nu}_2$ ). The couplet changes its sign when the angle between the transition moments of the monomers crosses the value of  $\sim 110^\circ$ . The amplitude of the couplet for the angle of the crossing point is zero. This results from an accidental degeneration of the excited states  $|K_1\rangle$  and  $|K_2\rangle$  by which both exciton CD bands compensate each other (crossing of the energies of both states). Determining the direction of the transition moments of the exciton transitions by polarized spectroscopy allows a reliable assignment of the transitions, in both cases.

For a quantitative calculation with eqn [32], a suitable interchromophoric distance has to be determined. Theoretically this distance is determined within the point dipole approximation where it has been assumed that  $|\underline{R}_{ij}|$  is large in comparison to the diameter of the monomeric units. In spite of the fact that the latter assumption is mostly not fulfilled, the exciton model has been applied with large success.

**Electronic circular dichroism for compounds without a chromophore** To determine the absolute configuration of compounds without a chromophore in the accessible spectral region one or more proper groups can be derivatized to obtain an appropriate chromophoric system. The substitution of dihydroxysteroids with two *p*-methoxybenzoates can be mentioned as an example. The substitution leads to an inherent dissymmetric chromophore for which the exciton chirality method can be applied. For chiral diols and amino alcohols another interesting possibility does exist. Complexing of these diols and amino alcohols with a transition metal

**Figure 9** The absolute configuration of *vic*-amino alcohols. The CD and UV spectra of *R*-alaninol (---), *R*-leucinol (.....), and *R*-phenylalaninol (—) in the presence of  $[\text{Mo}_2(\text{OAc})_4]$  referred to the total concentration of the *vic*-amino alcohols in DMSO at room temperature. The positive (negative) sign of the CE,  $\sim 330\text{ nm}$ , is related to the negative (positive) torsional angle of the N–C–C–O subunit. (Courtesy of Frelek J and Ruśkowska P, unpublished results.)

like dimolybdenum or dirhodium tetraacetate ( $\text{Me}_2(\text{O}_2\text{CCH}_3)_4$ ) leads to a chiral complex with a number of d–d and charge transfer transitions. The CD of the d–d transitions is determined by the absolute configuration of the diol and aminoalcohol units. The weakly absorbing chromophore is probably inherent dissymmetric with an allowed magnetic dipole transition (Figure 9) and, thus, easy to measure. One of the advantages of this method is that the complexes need not be isolated because only the signs of one or more of the CEs are needed. The disadvantages are the restriction of the rule to special classes of compounds and the often unknown assignment of the d–d transitions in the used spectral region.

**Quantum mechanical computation for electronic circular dichroism and vibrational optical activity** With the exception of the exciton chirality method for the development of sector and helicity rules, reference compounds are needed. Their absolute configuration has been usually obtained by X-ray analyses. The progress in numerical techniques of quantum mechanics nowadays allows performing computations of the rotational strength and its sign and, thus, the CD spectra with high reliability for CD

and also VCD for many classes of compounds. Here, the calculation of the rotational strength of more than one transition increases the reliability because not for all types of transitions the sign of the rotational strength can be obtained with the same quality. A large number of atoms of a molecule and the often existing large number of conformers also restrict the method. By a further improvement of the numerical techniques the application of empirical and semiempirical sector and helicity rules may hopefully decrease in their importance in the next years. For VCD spectroscopy, the empirical and semiempirical sector and helicity rules never have had the same importance as for electronic transitions. In Figure 10, an example for a computation is given in order to demonstrate the quality of calculated spectra.

The simplest form to characterize a chiral molecule was and is the specific optical rotation for one wavelength  $[\alpha]_D$ , e.g., in spite of the fact that  $[\alpha]_D$  is very sensitive against external influences because it is determined by a sum of many ORD sigmoid curves (eqn [21]; Figure 5), which belong to absorption bands lying far away, also in the UV spectral region. Until now it seemed that it is impossible to calculate  $[\alpha]_D^T$  with a sufficient reliability in order to use the specific rotation to more than a pure characterization

**Figure 10** The absolute configuration of mirtazapine from the comparison of the VCD and IR spectra of (–) mirtazapine and the calculated spectra (Gaussian 98, DFT level) of the *R*-enantiomer. The uppermost trace is the VCD noise. (Reproduced with permission from Freedman TB, Dukor RK, van Hoof PJCM, Kellenbach ER, and Nafie LA (2002) Determination of the absolute configuration of (–) mirtazapine using vibrational circular Dichroism. *Helvetica Chimica Acta* 85: 1160–1165.)

of a compound. But in the last years the quality of the computation of  $[\alpha]_D^T$  has much improved so that for some classes of compounds the absolute configuration was determinable. If this can be corroborated for diverse classes of compounds, the determination of the absolute configuration would be extremely simplified (see section on CD contra ORD).

#### Vibrational Circular Dichroism/Raman Optical Activity and Electronic Circular Dichroism – Partners or Opponents

The VCD, ROA, and ECD measure the same phenomenon. The ECD is well established since years whereas VCD and ROA are new and developing methods, especially also in their instrumentation. Therefore, the question arises whether the ECD can be superseded by VCD and RAO.

For the ECD only a small number of absorption bands are accessible in the UV/vis spectral region. Applying empirical rules and the results of the

theoretical computations with care allows determining the absolute configuration with high reliability. On looking closely one has to say that the local absolute configuration of the surroundings of the chromophore or of the chromophore itself is obtained for inherent symmetric and dissymmetric chromophores, respectively. Noncoupled or only weakly coupled overlapping chromophores probe an equal or similar surroundings. But as found for the  $n\pi^*$  and the  $\pi\pi^*$  transitions of the enone chromophore it happens that contradictory results are obtained from two chromophores. This shows the different sensitivities of different chromophores against small structural variations in their surroundings.

For the VCD and ROA a relatively large number of IR/Raman bands are accessible in the available spectral region. Normal vibrations are only very weakly coupled and thus, the information of the CD is localized to the surroundings of the normal coordinate. Because good empirical rules are not available, the quantum mechanical numerical computations are not an additional but, in general, the only information for the assignment of the absolute configuration. Restriction of the method lies within the scope of the quality of the calculation of the VCD/ROA spectra.

Comparing the information from ECD and VCD/ROA spectra is equivalent to a comparison of the different meanings of the VCD/ROA and the ECD chromophores as probes. The normal vibration is often the smaller chromophore. Thus, the information is more localized. But in contrast to the ECD, equal or similar VCD/ROA chromophores – functional groups in which a normal vibration is located – are often distributed over the skeleton of the whole molecule. In these cases the vibrational chromophores act as probes for a ‘mean’ geometry of the molecule whereas the ECD chromophore is a probe for itself or for its own surroundings. The correlation to the absolute configuration of the total molecule is unequivocal for ECD and VCD/ROA in most cases but for a number of questions their answers and the quality of answers are different. One obvious example is the different information of the analysis of vibrational progressions with the ECD and VCD. Whereas the ECD measures the effect of vibrations of the excited state, involved in the absorption process, the VCD yields information about vibrations of the electronic ground state. Thus, suitable chosen ECD and VCD are partners not opponents.

#### Conformational Analysis

The equilibria between chiral and achiral conformers of nonrigid molecules changes with temperature,

solvents, and by phase transitions because their energy difference  $\Delta E$  are in the order of  $k_B T$  ( $k_B$ , Boltzmann constant). Even compounds that are 'achiral' (racemic achiral), e.g., binaphthyl or chloroethane, possess chiral, or chiral and achiral conformers, respectively. ECD, VCD, and ROA have been proven to be very powerful techniques to determine these equilibria. *trans*-2-Chloro-5-methylcyclohexanone was the first example (Figure 7; originally via ORD spectra) where an equilibrium shift from the equatorial toward the axial conformation in a less polar solvent has been analyzed. The temperature dependence of  $\Delta\epsilon(T)$  has been used to evaluate the energies of conformers by a nonlinear fit of  $\Delta\epsilon(T)$  as a function of the Boltzmann factor  $\exp\{-\Delta E/k_B T\}$ . Nowadays an often applied method to handle the influence of conformations is the quantum mechanical calculation of the ECD, VCD, and ROA spectra taking the Boltzmann weighted distribution of conformers into consideration. Here, VCD seems to be superior to the ECD analysis. ECD and VOA are superior to analyses of absorption spectra, especially when the CD spectra of conformers have opposite signs by which the sensitivity of the method is increased.

### Association and Aggregation

Association of molecules changes their  $\Delta\epsilon$  as has been proven for metal complexes, charge transfer complexes, Lewis acids, etc. In any case, complex formation can be followed by the variation of the CD. Molecular association is the first step to an aggregation and, furthermore, is the presupposition for supramolecular structures. Compounds with intermolecular exciton interaction, e.g., carotenoids or cyanine dyes, have been successfully analyzed. The spontaneous association to chiral associates from achiral compounds, e.g., cyanines, have been proven and analyzed with the help of ECD spectroscopy. In this context, the successful CD analyses with Langmuir–Blodgett films as well as the analyses of membranes have to be mentioned where suprastructural chirality can also emerge from achiral monomers.

### Macromolecules

Conformations and structures of polymers and biopolymers are accessible by ECD, VCD, and ROA spectroscopy. Suitable chromophores for the ECD are aromatic amino acids, the bases of nucleic acids, and the peptide bonds in the spectral region  $\sim 270$  nm and from 230 down to 160 nm. The determination of the  $\alpha$ -helix content of proteins was

one of the first successful applications. In addition to other features, VCD and ROA provide information about the secondary and tertiary structure of polypeptides or the base stacking of nucleic acids. As an example, ROA and Raman spectra of poly(L-lysine) in its  $\alpha$ -helical, disordered, and in the  $\beta$ -sheet structure are given in Figure 11. Even viral nucleic acids and proteins of intact viruses have been successfully identified in complex mixtures.

**Figure 11** ROA ( $I^R - I^L$ ) and backscattered Raman ( $I^R + I^L$ ) spectra of the  $\alpha$ -helical (A), disordered (B), and  $\beta$ -sheet (C) poly(L-lysine) at 20°C. (Reproduced with permission from Barron LD, Blanch EW, McColl IH, *et al.* (2003) Structure and behavior of proteins, nucleic acids and viruses from vibrational Raman optical activity. *Spectroscopy* 17: 101–126.)

### Pharmaceutical Applications

It is well known that right and left handed molecules of chiral drugs can differ dramatically in their pharmaceutical impact. Even a small racemic fraction in a chiral drug can be a dangerous impurity. Therefore, the determination of the optical purity is one of the most important applications of the chiroptical analysis. Specific techniques are needed in order to detect a very small percentage of a chiral compound in a mixture of other chiral compounds (see section on Polarimetry and CD detectors in liquid chromatography). A second analytical problem concerns the conversion of pure enantiomers into the other, often unacceptable form in a biological milieu. The high potential of VCD for determining the optical purity and the absolute configuration of newly synthesized chiral molecules intended for medical application has attracted increasing attention of this newer technique in the chemical and pharmaceutical industries (see section on Macromolecules).

### Time-Resolved Circular Dichroism

CD instruments have not primarily been developed for chiroptical kinetic analyses. In this context, racemization kinetics, complexing of metal ions, and also folding processes, e.g., of proteins, are an essential field of chiroptical analyses. The modulation technique as well as the scanning operations of the spectra restrict kinetic analyses to times not faster than some 10–100 ms. New developments, using diode array technologies, do not seem to be available at the moment. Instruments aimed for the nanosecond time regime are individual constructions generally incapable of and unavailable for systematic studies, nowadays, in spite of the fact that very interesting results can be expected by this technique.

### Indirect Methods of Chiroptical Analysis

The assignment of the absolute configuration with the help of sector and helicity rules is often seriously restricted. The assignment by quantum mechanical methods is now, as before, time consuming and not always available. Therefore, a way forward may have to be sought through new methods.

### NMR Measurements of Diastereomers with Substituents of Known Absolute Configuration

The NMR spectroscopy of diastereomeric compounds with unknown absolute configuration, derivatized with suitable substituents of known absolute configuration, has been introduced as a new

‘indirect’ chiroptical method that also allows determining the optical purity.

### Chiral Induction of Cholesteric Phases – Circular Dichroism and Selective Reflection

A chiral compound, dissolved in a nematic liquid crystal phase, transforms this phase into a chiral phase that is very often a chiral nematic – cholesteric – phase. Under the same condition of concentration and temperature two enantiomers induce helical structures with the same pitch but of opposite sign. The helical pitch  $p$  is for low concentrations of the dopant a linear function of mole fraction  $x$ . The molecular measure for the chiral induction is the helical twisting power (HTP):

$$\text{HTP} = px^{-1} \quad [33]$$

The pitch can be obtained by the CANO method or from the wavelength  $\lambda_0$  of the maximum of the selective reflection of circularly polarized light by

$$\lambda_0 = \bar{n}p. \quad [34]$$

$\bar{n} = (n_e + n_o)/2$  is an average of the refractive indices  $n_e$  and  $n_o$  of the ordinary and extraordinary rays. In spectral regions far away from the selective reflection a CD can be observed within the absorption bands of dopants in the cholesteric phase. Even achiral molecules, dissolved in a cholesteric phase, give rise to a CD. In spite of the complex origin of the HTP, correlations between the absolute configuration and the sign of the HTP have been found experimentally, especially for ‘form chiral’ molecules (inherent dissymmetric molecules). These phenomena may be an important field for prospective chiroptical analyses. Because of the broad research field about the chiral induction it is impossible to go into details, here.

## Analytical Applications

### Polarimetry

The unambiguous determination of enantiomeric excess and optical purity is an important task for the characterization and application of nonracemic chiral compounds. There are two different principles available: the determination of chiroptical properties such as CD, ORD, or the specific rotation  $[\alpha]_\lambda^T$  or to analyze the diastereomeric interaction with other chiral environments. The enantiomeric excess

$$\%ee = \frac{c_R - c_S}{c_R + c_S} 100 \quad [35]$$

can be obtained via the optical purity

$$P = \frac{[\alpha]^T}{[\alpha]_{\lambda, \max}^T} \quad [36]$$

if there is no diastereomeric interaction between the enantiomers in the enantiomeric mixture (e.g., complexing).  $c_R$  and  $c_S$  are the concentrations of the *R* and *S* enantiomer, respectively.  $[\alpha]^T$  is the specific rotation for the enantiomeric mixture and  $[\alpha]_{\lambda, \max}^T$  the specific rotation of the pure enantiomer.  $[\alpha]$  is a function of temperature, concentration (density of a neat liquid), and the solvent. The optical rotation is mostly measured far away from absorption bands – standard is the sodium D-line – in spite of the fact that there the optical rotation is small and often not very characteristic.

There are a number of requirements to the accuracy of the method because the two borderline cases, the racemic mixture (50:50) and the pure enantiomer (100%ee), have to be determined with high accuracy. The accuracy of a polarimetric measurement is  $\sim 10^{-3} - 10^{-4}$  degree. For small values of  $[\alpha]^T$  a suitable concentration and path length have to be chosen. For large values of  $[\alpha]_{\lambda, \max}^T$  any measured angle can be  $\alpha \pm 180n^\circ$ . To check  $n$ , a dilution experiment has to be performed. Furthermore, an independently proven absolute specific rotation  $[\alpha]_{\lambda, \max}^T$  has to be available. Also the purity of a compound is of importance. An enantiomeric excess counts as an impurity. The optical purity is only equal to the enantiomeric excess if and only if the conditions given above are fulfilled.

For a characterization within a series of compounds often polarimetry supersedes CD spectroscopy because the chosen concentration for its measurement is not restricted by a too high absorption. The broad acceptance of the polarimetric standardization of chiral compounds always has been a motivation for improvements of polarimeters. Especially for the daily routine work there is a requirement for instruments with high convenience (see section on Polarimetry and CD detectors in liquid chromatography).

### Polarimetry and Circular Dichroism Detectors in Liquid Chromatography

A polarimetric equipment is an important detector in liquid chromatography. The combination of an  $[\alpha]_{\lambda, \max}^T$  measurement combined with a detection of the UV absorption allows to determine the optical purity even in the case of an incomplete chromatographic enantiomeric separation. The use of CD as a chromatographic detector is limited in liquid

chromatography. One of the most serious experimental limitations is the very small CD signal because the concentrations must be kept very low in a chromatographic process and the path lengths, viewed across the exit tubes, is short. Furthermore, the scanning time for a spectrum has to be short in comparison to the retention time if the analysis needs a complete CD band in order to gain more information. In spite of these limiting facts the CD detector has been often applied with success. The measurement of the dispersion of  $\Delta\epsilon cd$ , or with less information the optical rotation, and the absorbency  $\epsilon cd$  have been used for optical purity online analyses by deconvolution of the overlapping CD peaks of enantiomers. Furthermore, enantiomerization during the chromatographic process can be analyzed. In order to overcome the limitation of the time-consuming registration of a spectrum a simultaneous measurements of a CD spectrum could be of interest (see section on Time-resolved circular dichroism).

### Properties of Chiral Phases

New and promising fields are the chiroptical analyses of chiral crystals, chiral liquid crystal phases, chiral membranes, Langmuir–Blodgett films, chiral surfaces, etc. Their chirality is caused by the molecular chirality and the suprastructural chirality of the phase. Because the spatial extension of the structures of the suprastructural chirality is often about three orders of magnitude larger than molecular diameters, the spectral regions of chiroptical phenomena for both levels of chirality are different.

From our daily life it is well known that chiral objects like spiral staircases or flowers look different from different directions. Therefore, it seems evident that chiral molecules and chiral suprastructural phases are anisotropic, too. Until now, chiroptical methods have been only very sparsely applied to chiral anisotropic systems because of serious experimental problems. At first one has to draw attention to artifacts induced by the always existent linear dichroism and birefringence of anisotropic systems (elliptical dichroism and birefringence). Secondly, objects without symmetry do not allow to measure directly ‘chiral and achiral anisotropies’ without additional requirements. That is, new techniques and unequivocal definitions are needed to decompose the results of measurements with chiral anisotropic phases into ‘chiral’ and ‘achiral’ components. A minimum of symmetry is needed to adapt suitable situations where the CD and ORD as chirality measurements of anisotropic systems can be observed directly.

### Pretransitional Phase Effects

In the isotropic phase near the phase transition to a chiral liquid crystal phase a strong increase of the optical rotation has often been observed. The so-called pretransitional phase effect announces a structural change by approaching the phase transition temperature. Corresponding CD measurements do not exist because the extreme increase of the optical rotation has been measured always with neat compounds where large absorption prohibits CD measurements. For induced chiral phases with low concentrations of chiral dopants pretransitional phase effects have not been observed.

### Circular Dichroism of Chiral Anisotropic Phases without Suprastructural Chirality

The chiral anisotropy of a phase is the consequence of the anisotropy of the results of chirality measurements with oriented molecules, i.e., information about chiral molecules when viewed from different directions. This is of interest, e.g., when two molecules, oriented with respect to each other, interact in an asymmetric synthesis.

A sufficient amount of oriented chiral molecules can be obtained in an induced cholesteric liquid crystal phase if the induced helical structure has been untwisted by an electric field. In the following description tensors are needed for the sake of simplicity (At least there are three tensors required: the transition moment tensor  $D_{ij}$  (absorption tensor  $\varepsilon_{ij}$ ), the rotational strength tensor  $R_{ij}$  (circular dichroism tensor  $\Delta\varepsilon_{ij}$ ), and the order tensor  $g_{ij33}$  ( $i, j = 1, 2, 3$ ). If the molecules do not possess any symmetry, the principal axes of all of these tensors are differently oriented with respect to the molecular frame (the coordinate system in which only the three diagonal elements of a tensor are different from zero.) The only tensorial property, needed here explicitly, is the existence of three coordinates (components) of a tensor with respect to three specially chosen mutually perpendicular axes. This means that three information instead of one information about a molecule are needed: instead of one CD value, namely  $\Delta\varepsilon$ , three CD values, namely  $\Delta\varepsilon_{ii}$  ( $i = 1, 2, 3$ ), have to be introduced.  $\Delta\varepsilon$  is then one-third of a sum of the three so-called tensor coordinates of the CD tensor:

$$\Delta\varepsilon = \frac{1}{3}(\Delta\varepsilon_{11} + \Delta\varepsilon_{22} + \Delta\varepsilon_{33}) \quad [37]$$

A coordinate  $\Delta\varepsilon_{ii}$  for  $i = 1, 2$ , or  $3$  is the result of a CD measurements with a light beam propagating along the axis  $i$  of the molecule. In addition, all molecules in each measurement have to be parallelly oriented with respect to the axis  $i$  and the ensemble

of the molecules have to be rotationally symmetrically distributed about the chosen axis  $i$ . The latter condition is fulfilled with a light beam propagating parallel to the optical axis of a uniaxial phase. It is not fulfilled for a light beam propagating perpendicular to its optical axis. Here the result is of ‘mixed symmetry’, i.e., a mixture of a scalar (achiral) and a pseudoscalar (chiral) information.

The CD of a uniaxial phase with a light beam propagating parallel to the optical axis of the phase, the ACD, is then given by

$$\Delta\varepsilon^A = g_{1133}^* \Delta\varepsilon_{11}^* + g_{2233}^* \Delta\varepsilon_{22}^* + g_{3333}^* \Delta\varepsilon_{33}^* \quad [38]$$

where the orientational distribution coefficients  $g_{ii33}^*$  are measures of the order of the molecules in a uniaxial phase of partially oriented molecules (eqns [39] and [40]). The orientational distribution coefficients are correlated with the earlier introduced Saupe order parameters by

$$S^* = \frac{1}{2}(3g_{3333}^* - 1) \quad \text{and} \quad D^* = \frac{\sqrt{3}}{2}(2g_{2233}^* + g_{3333}^* - 1) \quad [39]$$

In addition the following relations hold:

$$0 \leq g_{ii33} \leq 1 \quad \text{for } i = 1, 2 \text{ or } 3 \quad \text{and} \quad \sum_{i=1}^3 g_{ii33}^* = 1 \quad [40]$$

The convention  $g_{3333}^* \geq g_{2233}^* \geq g_{1133}^*$  allows to introduce the ‘orientation axis ( $x_3^*$ )’ of a molecule, i.e., ‘the best ordered molecular axis in an anisotropic phase’. The  $g_{ii33}^*$  ( $i = 1, 2, 3$ ) are given in their principal axes, otherwise nondiagonal elements of  $\Delta\varepsilon_{ij}$  ( $i = 1, 2, 3$ ) are required in eqn [38]. The  $\Delta\varepsilon_{ij}^*$  are complicated functions of the involved electric and magnetic dipole and the electric quadrupole transition moments. The contribution of the electric dipole, magnetic dipole, and the electric quadrupole transition moments can be obtained for the transition  $|0\rangle \rightarrow |n\rangle$  directly by

$$\Delta_1 = \frac{1}{2}(\Delta\varepsilon_{11}^* - \Delta\varepsilon_{22}^* - \Delta\varepsilon_{33}^*) = -\frac{1}{2}B\bar{v} \sum_n \text{Im}\{\langle \mu_1 \rangle_{0n} \times \langle m_1 \rangle_{n0} \} F^{0n}(\bar{v}) + \Delta\varepsilon_{11}^{\mu Q} \quad [41]$$

$$\Delta_2 = \frac{1}{2}(\Delta\varepsilon_{22}^* - \Delta\varepsilon_{11}^* - \Delta\varepsilon_{33}^*) = -\frac{1}{2}B\bar{v} \sum_n \text{Im}\{\langle \mu_2 \rangle_{0n} \times \langle m_2 \rangle_{n0} \} F^{0n}(\bar{v}) + \Delta\varepsilon_{22}^{\mu Q} \quad [42]$$

$$\Delta_3 = \frac{1}{2}(\Delta\varepsilon_{33}^* - \Delta\varepsilon_{11}^* - \Delta\varepsilon_{22}^*) = -\frac{1}{2}B\bar{v} \sum_n \text{Im}\{\langle \mu_3 \rangle_{0n} \times \langle m_3 \rangle_{n0} \} F^{0n}(\bar{v}) + \Delta\varepsilon_{33}^{\mu Q} = -\frac{3}{2}\Delta\varepsilon - \Delta_1 - \Delta_2 \quad [43]$$

The three diagonal elements  $\Delta\epsilon_{ii}^{\mu Q}(\bar{\nu})$  ( $i = 1, 2, 3$ ) are proportional to products of electric dipole times electric quadrupole transition moments. They do not contribute to the isotropic CD because the sum over the three coordinates  $\Delta\epsilon_{ii}^{\mu Q}(\bar{\nu})$  ( $i = 1, 2, 3$ ) is zero.  $\Delta\epsilon_{ii}$ , measured for oriented guest molecules in ordered liquid crystal phases, yield spectroscopic and structural information and, has been used, especially for the check of sector and helicity rules. First numerical quantum mechanical calculations of the CD tensor coordinates  $\Delta\epsilon_{ii}$  have been published recently.

### Chiral Crystals

Solid-state CD spectra provide information on chiral conformations, suprastructural chirality of solid phases, packing effect in crystals, and absolute configuration of the molecular and the phase chirality. Especially the anisotropy of chirality measurements – the pseudoscalar information – of small molecules and also biopolymers has been obtained, which are completions to the results of ACD measurements of noncrystalline phases with oriented molecules (see section on Circular dichroism of chiral anisotropic phases without suprastructural chirality). For the general case of crystals without or with low symmetry the measured CD is a mixture of achiral and chiral information, in principle – a function of a pseudoscalar and a scalar contribution – because the eigenstates of light are elliptically polarized. In this context one should remember that also for achiral crystals ( $m$ ,  $mm2$ ,  $\bar{4}$ ,  $\bar{4}2m$ ) or molecules with a special long-range order a CD can be obtained, which is by no means caused by chirality. In order to avoid mixed information there are at least three possibilities:

1. To measure a crystal – or general any phase – along the optical axis of a uniaxial phase where the eigenstates are circularly polarized.
2. To measure a powdered crystalline material with isotropically distributed crystallites, e.g., pressed in KBr or as a suspension in Nujol.
3. To measure along an arbitrary direction apart from the optical axis/axes. Here a technique is needed which allows to decompose the result into its pseudoscalar (chiral) and scalar (achiral) contribution.

**Isotropically distributed powdered crystals** Powdered crystalline material pressed in KBr or as a suspension in Nujol with isotropically distributed chiral crystals should yield the CD of isotropically distributed molecules and the CD of the isotropically distributed ‘crystals with their suprastructural

chirality’. Until now, a decomposition into these two effects has not been performed. One of the most difficult problems for such CD measurements is an always existing residue of anisotropy by incompletely distributed powdered material or by scattering of crystallite surfaces, which leads to an azimuth dependent CD of the sample. However, for many compounds the CD has been successfully analyzed with this technique. In spite of the success of this method there are a number of unresolved problems. The measured ‘isotropic CD’ of these crystal powders has been corrected with equations derived with the Jones Calculus for homogeneous material and for coherent light waves. Furthermore, no contribution of a tensorial contribution of the anisotropy of the CD of crystallites has been taken into account. Here, artifacts originated by the artificial anisotropy of grounded material and their inhomogeneities need further considerations.

**Crystals** Measurements with enantiomorphic crystals along an optical axis have often been reported in biographies of crystal optics. Measuring the ORD and CD for uniaxial and biaxial crystals in any direction apart from the optical axis (axes) are up to now one of the most difficult experiments (see section on Experimental equipments). J. Kobayashi’s extended HAUP method is time consuming but very successful. CD, CB, linear dichroism (LD), and linear birefringence (LB) can be obtained in one and the same experiment. Most of the information has been obtained only for a single wavelength because no suitable equipment is available to determine the dispersion automatically. Besides optically active inorganic crystals, crystals of small chiral molecules and especially biopolymers have been analyzed as, e.g., crystalline glyoxylamide,  $\beta$ -lactams, aspartic acid, glutamic acids, poly-L-lactic acid, and lysozyme. The effect of freezing of conformations in the crystalline state and the anisotropy of the chirality measurement of an oriented helix strand have been proven.

### Circular Dichroism of Chiral Anisotropic Phases with Suprastructural Chirality

**Amorphous phases** A new field of applications of chiroptical analyses is the search of chiral structures in Langmuir–Blodgett films or thin films of polymers, membranes, and ‘chiral surfaces’, surfaces on which a few chiral molecules are adsorbed. The recently published technique of reflectivity CD may allow systematic analyses of chiral metal surfaces. This field is too new to be summarized and, therefore, some selected papers have been cited in the Further reading section.

**Liquid crystals** There is a broad field for chiroptical analyses with chiral liquid crystal phases. Because it is beyond the scope of this article to discuss all types of chiral liquid crystals, only two chiral phases with a simple suprastructural chirality will be mentioned here, which are of special interest also for display technology. First, there is the chiral nematic  $N^*$ -cholesteric phase mostly used in twisted nematic (TN) displays. Here, the long-range orientational order does possess a helical structure of chiral and in an induced phase of chiral and achiral molecules. Their longest axes, their orientation axes, are oriented in the mean perpendicular to the helix axis. The helix is then obtained by the periodic rotation of the orientation axes of the molecules about the helix axis. Here again the two levels of chirality, the molecular and the suprastructural phase chirality, are involved. In the second important phase, the smectic  $C^*$  phase, a helical order is produced by molecules that are tilted with their long axis (orientation axis) against the normal of the smectic layers. The chiral structure of the phase is obtained by a periodical rotation of the tilt angle in the smectic layers about the optical axis – the helix axis – of the phase.

Until now, only a few chiroptical analyses have been performed with liquid crystal phases. This has again its origin in the experimental problems of CD measurements with anisotropic phases. Besides all those problems that appears in context with ORD and CD measurements of crystals with low symmetry (see section on HAUP method) one has to overcome the falsification of results by the intense scattering of the liquid crystal phases. To some extent this scattering can be subdued by measuring thin films with a thickness in the order of micrometers.

## Experimental Equipment

Either the difference of two absorption coefficients ( $\Delta\epsilon$ ) and the difference of two refractive indices ( $\Delta n$ ) of the circularly polarized eigenstates or the state of polarization – the ellipticity and the optical rotation – of the light beam leaving the sample have to be measured. Nowadays, experimentally preferred are the determinations of  $\Delta\epsilon$  and the optical rotation.

The optical rotation can be obtained from the change of the azimuth angle of an analyzer (Figure 12) in an originally crossed polarizer–analyzer system. The half-shade device of historical instruments is substituted by a modulator Mo for the state of polarization, which is transformed into an intensity modulation by a following analyzer. The accuracy with common available polarimeters and spectral polarimeters lies between  $10^{-4}$  and  $10^{-3}$  degrees.

**Figure 12** Block diagram of a spectral polarimeter (a), a polarimeter (b), and the HAUP spectrometer (c). (S = source of radiation: xenon lamp (a); sodium or mercury lamp (b), laser (c); M/F = monochromator (a) or filter (b, c); P = polarizer (a, b, c); c = sample cell C<sub>1</sub> (a, b) or crystal plate Cr (c); Mo = modulator: half-shadow equipment (a, b); A = analyzer (a, b, c); PM = photomultiplier (a, b, c); EL-R = electronic device/computer/recorder (a, b, c).)

**Figure 13** Block diagram of a CD spectrometer with a periodic variation of the state of polarization and by this an intensity modulation by the absorption difference of the sample for the UV/vis (a) and the IR (b) spectral region if the optical elements are suitable chosen (S = source of radiation; M/F = monochromator (a, b), or Fourier transform interferometer (b); P = polarizer; PEM = photoelastic modulator; C = sample cell; PM = photomultiplier (a, b) or another detector (b); EL-R = electronic equipment/computer/recorder).

ECD and VCD spectrometers modulate (Mo) the state of polarization of the incident light. Through CD of the sample the polarization modulation is transformed into an intensity modulation (Figure 13). The amplitude of the modulated intensity is proportional to the CD. Nowadays, ECD spectrometers possess a fully developed technology. Therefore, only about a few instrumental developments have been reported recently. There are efforts to subdue the sensitivity to linear dichroism (LD) and birefringence (LB) in order to measure the CD of chiral anisotropic crystals (ACD). But the use of a selected artifact-free optical modulator (Mo) and a rotation of the sample were until now only of limited success. In order to gain intensity in an ECD spectrometer, both orthogonally polarized light beams leaving the polarizing system P (Figure 13) have been used to measure the CD signal. The symmetry of both beams can be used to suppress artifacts induced

by anisotropic samples. The dissymmetry factor  $g$  (eqns [29] and [30]), a reliable measure for an estimate of the sensitivity of CD instruments, lies for the UV/vis region between  $10^{-7}$  and  $10^{-6}$  whereas for the IR region a value  $\sim 10^{-6}$  can be obtained.

To increase the sensitivity of FD CD fluorescence spectrometer a new equipment for the excitation of the sample with left ( $I_L$ ) and right ( $I_R$ ) circularly polarized light (eqn [44]) has been developed by the use of an ellipsoidal mirror for the exciting light and a polarizing equipment for the emitted light. The contribution of 'wrongly' polarized light has been strongly reduced. And, thus the results essentially improved:

$$\frac{I_L - I_R}{I_L + I_R} \quad [44]$$

VCD instruments, based also on the principles depicted in **Figure 13**, are in comparison to the ECD instruments, relatively new products on the market. Thus, there have been further developments. Two of them should be mentioned, namely, the use of the Fourier transform technology and the use of a second PEM with and without a second polarizing element. This 'dual polarization modulation (DPM)' method increases the quality of the VCD spectra. Also, the Raman spectrometers for ROA, with which the difference of scattered left and right circularly polarized Raman light is measured, have been developed to a standard that allows systematic chiroptical analyses, nowadays.

The determination of the optical constants CD, CB, LD, and LB of crystals of low symmetry in any direction apart from the optical axis/axes allows the high-accuracy universal polarimeter (HAUP) consisting of a polarizer, an analyzer (**Figure 12**) and as for any polarimeter an 'electronic half-shade' device as a modulator to increase the signal to noise ratio. A plane-parallel plate of a crystal is oriented with its linear azimuth, symmetry azimuth, or minimum azimuth (Using the nomenclature of G. Szivessy and Cl. Münster. These three azimuths converge to the azimuth of the eigenpolarization of, e.g., a uniaxial crystal.) approximately parallel to the almost crossed polarizer and analyzer. The fit of the intensity as a function of two angles, the angles between the polarizer and the analyzer and, e.g., the minimum azimuth of the crystal, respectively, allows determining all four optical constants. Artifacts induced by the experimental equipment can be measured independently without the crystal plate. The time consuming technique impeded the applicability of the HAUP instrument to measure the wavelength dependence which is often needed for an interpretation of molecular systems.

## Introduction

A wide variety of C1–C2 halocarbons have been identified in the Earth's atmosphere at concentrations ranging from a few to several hundred ppt (parts per trillion, or parts in  $10^{12}$ ). Many of the species identified are of natural origin, being produced in the oceans (e.g.,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{Br}$ ,  $\text{CH}_3\text{I}$ ,  $\text{CHBr}_3$ ), from the natural burning of biomass ( $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{Br}$ ), and even from geochemical processes ( $\text{CF}_4$ ). With the exception of  $\text{CH}_3\text{Cl}$ , which is present at  $\sim 500$  ppt, the natural background mixing ratios of these species are quite low, typically less than 10 ppt, and consequently their contributions to global processes such as stratospheric ozone depletion and global warming are relatively small. However, it has become apparent that the halocarbon content of the lower atmosphere has been significantly perturbed during the twentieth century as a result of expanding production and emission of an ever-increasing number of synthetic compounds, most notably the chlorofluorocarbons or CFCs. Commercial production of CFCs began in the 1930s and they have subsequently found widespread use in refrigeration, foam blowing, and aerosol propellant applications. Other halocarbons have been used as industrial solvents, chemical feedstocks, and as cleaning/degreasing agents ( $\text{CH}_3\text{CCl}_3$ ,  $\text{CCl}_4$ ,  $\text{CH}_2\text{Cl}_2$ ,  $\text{C}_2\text{Cl}_4$ ), for fire-fighting ( $\text{CBrClF}_2$ ,  $\text{CBrF}_3$ ), and as fumigants in the agricultural industry ( $\text{CH}_3\text{Br}$ ). Several halocarbons are also emitted as by-products of industrial processes ( $\text{CF}_4$ ,  $\text{C}_2\text{F}_6$ ,  $\text{CHF}_3$ ). This article will focus on these synthetic halocarbons, discussing atmospheric sampling methods, analytical techniques, and their effect on stratospheric ozone and climate.

## Environmental Concerns

Concern over the build-up of halocarbons in the atmosphere began in the early 1970s when it was proposed that long-lived CFCs could be photodissociated in the stratosphere, releasing chlorine atoms capable of ozone destruction. Up until that time, being inert, nonflammable, and nontoxic, CFCs

had been considered benign and their production and range of applications had grown considerably since their introduction in the 1930s. By 1974, the combined production of the two major CFCs,  $\text{CCl}_2\text{F}_2$  (CFC-12) and  $\text{CCl}_3\text{F}$  (CFC-11), had reached over 800 000 metric tons per year. However, despite extensive research driven by considerable public and political concern, it was not until the mid-1980s that the first evidence of significant ozone depletion was found in the unexpected form of the Antarctic ozone hole. The ozone hole was inextricably linked to reactions involving chlorine and bromine atoms, and this led to the signing of the Montreal Protocol in 1987. This treaty, and subsequent amendments, imposed restrictions on the consumption of substances thought to contribute to ozone depletion, most notably the CFCs, halons, and the chlorinated solvents,  $\text{CH}_3\text{CCl}_3$  and  $\text{CCl}_4$ .

Following the Montreal Protocol, industry was forced to look for suitable alternatives to the banned compounds and amongst them the prime candidates were hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs). Both types of compound contain at least one C–H bond that renders them susceptible to attack by hydroxyl radicals (OH) in the Earth's troposphere, thereby shortening their atmospheric lifetimes and reducing their potential threat to stratospheric ozone. Although their ozone depletion potentials (ODPs) are generally much smaller than those of the CFCs, HCFCs still contain chlorine and are themselves regulated under the Montreal Protocol, with phase-out scheduled for 2030. HFCs are generally regarded as more acceptable replacements for CFCs as they contain no chlorine. Under the auspices of AFEAS (Alternative Fluorocarbon Environmental Acceptability Study) and PAFT (Programme for Alternative Fluorocarbon Toxicity Testing), the environmental impact of HCFCs, HFCs, and their degradation products was thoroughly investigated before significant commercialization began (see Table 1).

Another group of chemicals regulated by the Montreal Protocol is the halons. Halons are fully halogenated, bromine-containing, CFC analogs, used as fire extinguishing agents. Despite their relatively low abundance, halons are an important source of stratospheric bromine. Atom for atom, bromine is 40–100 times more efficient than chlorine at depleting ozone, and is involved in 25–50 and 10% of

**Table 1** Atmospheric lifetime, ozone depletion and global warming potentials of the major atmospheric halocarbons

Formula	Common name	Lifetime (years)	ODP <sup>a</sup>	GWP <sup>b</sup>

<sup>a</sup> Ozone depletion potential relative to CFC-11.<sup>b</sup> Global warming potential relative to CO<sub>2</sub> for a 100-year time frame.Adapted from WMO (World Meteorological Organisation) (2003) *Scientific Assessment of Ozone Depletion: 2002*. Global Ozone Research and Monitoring Project, Report No. 47, Geneva.

ozone loss in polar regions and mid-latitudes, respectively. Halons account for 30–40% of bromine in the stratosphere. The other major source of stratospheric bromine (~50%) is methyl bromide (CH<sub>3</sub>Br), a chemical used as an agricultural fumigant. Despite also having significant natural sources and a relatively short lifetime (<1 year), CH<sub>3</sub>Br was added to the Montreal Protocol in 1992.

A second concern regarding the accumulation of halocarbons in the atmosphere is their potential effect on climate. Many halocarbons are efficient absorbers of infrared radiation, particularly in the atmospheric ‘window’ region (800–1200 cm<sup>–1</sup>) where naturally occurring species such as CO<sub>2</sub> and water vapor do not absorb strongly. In the atmosphere these compounds trap radiation emitted from the Earth’s surface, thereby contributing to the warming of the lower atmosphere, the so-called greenhouse effect. With their long atmospheric lifetimes certain halocarbons, most notably the perfluorocarbons (PFCs) and SF<sub>6</sub>, are among the most potent greenhouse gases known, with global warming potentials (GWPs) several orders of magnitude higher than that of CO<sub>2</sub>. PFCs, HFCs, and SF<sub>6</sub> do not participate in ozone depletion so are not controlled by the Montreal Protocol, but they have recently been included in the Kyoto Protocol, which aims to reduce emissions of greenhouse gases by 2008–2012.

### Stratospheric Ozone Depletion

In the troposphere, CFCs are unreactive and are not susceptible to the normal degradation mechanisms

such as reaction with OH radicals, rainout, or surface deposition. Furthermore, the short wavelength ultraviolet radiation required to break C–Cl bonds does not penetrate into the troposphere, being absorbed at higher altitudes by ozone and molecular oxygen. Consequently, CFCs have long atmospheric lifetimes and are slowly transported to the stratosphere where photolysis can occur, for example:

Cl atoms can participate in catalytic cycles leading to ozone destruction. Examples include:

and

Observed ozone losses are highly variable in both space and time. The global average total column ozone in the late 1990s was ~3% below pre-1980

values. However, much greater losses are seen in polar regions, particularly in Antarctica, where losses of up to 70% have been recorded. During austral winter, a vortex of cold, sinking air forms over Antarctica, which persists for several months. Temperatures inside the vortex become sufficiently cold for polar stratospheric clouds to form and reactions on the surface of these clouds convert unreactive chlorine reservoirs (HCl, ClONO<sub>2</sub>) into photolytically labile species (Cl<sub>2</sub>, HOCl). Although stable in the dark winter conditions, Cl<sub>2</sub> and HOCl are rapidly photolyzed in spring releasing Cl atoms. The most important catalytic cycle at polar sunrise, responsible for ~70% of ozone loss, involves the Cl<sub>2</sub>O<sub>2</sub> dimer:

## Halocarbon Production, Applications, and Sources

CFCs were developed in the late 1920s by scientists at General Motors/Frigidaire as a safe alternative to traditional refrigerants such as sulfur dioxide and ammonia. Being nontoxic, nonflammable, noncorrosive, energy efficient, and inexpensive, CFCs proved to be ideal and soon captured much of the global refrigeration and air conditioning market. They have also found widespread use as foam blowing agents, aerosol propellants, and chemical solvents (see Table 2). Global production of CFCs reached a maximum in the late 1980s but has declined rapidly in response to the Montreal Protocol. In the developed world, production of the three most widely used CFCs (11, 12, 113) fell from over 1000 Gg in 1987 to just 30 Gg by 2001.

HCFC-22 (CHClF<sub>2</sub>) has been widely used since the 1930s for refrigeration, air conditioning, and as a chemical feedstock. Annual production continued to rise throughout the latter part of the twentieth century reaching over 250 Gg by the mid-1990s. Production of other HCFCs, most notably CH<sub>3</sub>CClF<sub>2</sub> (HCFC-142b) and CH<sub>3</sub>CCl<sub>2</sub>F (HCFC-141b), began in earnest in the 1990s coinciding with the phase out of CFCs. Global production of HCFC-141b, for example, rose from ~0.1 Gg in 1990 to 135 Gg in 2000. HCFCs 142b and 141b are primarily used as foam blowing agents (see Figure 1).

**Table 2** Principle applications and major industrial sources of halocarbons

Chemical	Application/source
CFC-11	Foam blowing, aerosol propellant
CFC-12	Refrigeration, aerosol propellant
CFC-113	Solvent, cleaning agent
CH <sub>3</sub> CCl <sub>3</sub>	Cleaning/degreasing agent
CCl <sub>4</sub>	Chemical feedstock/solvent
Halon-1211	Fire extinguishing
Halon-1301	Fire extinguishing
CH <sub>3</sub> Br	Fumigation, leaded petrol
HCFC-22	Refrigeration, air conditioning, feedstock
HCFC-141b	Foam blowing
HCFC-142b	Foam blowing
HFC-23	HCFC-22 production
HFC-134a	Refrigeration, air conditioning
HFC-152a	Refrigeration, chemical feedstock
HFC-143a	Refrigeration
HFC-125	Refrigeration
CF <sub>4</sub>	Aluminum production, electronics
C <sub>2</sub> F <sub>6</sub>	Aluminum production, electronics
SF <sub>6</sub>	Electrical insulation, magnesium smelting

In common with most HCFCs, large-scale production of HFCs did not begin until the 1990s. The most widely used is CF<sub>3</sub>CH<sub>2</sub>F (HFC-134a), which is the favored replacement refrigerant for CFC-12. Global production rose from practically zero in 1989 to 135 Gg in 2001. Another important HFC (CHF<sub>3</sub>, HFC-23) is released as a by-product during the manufacture of HCFC-22. HFC-23 has a particularly long atmospheric lifetime (270 years) and, on a per molecule basis, is one of the most potent greenhouse gases detected in the atmosphere to date.

Halons 1211 (CBrClF<sub>2</sub>) and 1301 (CBrF<sub>3</sub>) were developed in the 1940s and found widespread use in fixed (1301) and portable (1211) fire extinguishing systems. A third halon, CBrF<sub>2</sub>CBrF<sub>2</sub> (H-2402), was produced in the former Soviet Union, although in much smaller quantities. Global production of the major halons peaked in the late 1980s and had been phased out in all but a handful of developing countries by 1994. CH<sub>3</sub>Br is produced by both natural and anthropogenic processes. Major sources to the atmosphere include agricultural fumigation, biomass burning, the oceans, and a number of terrestrial ecosystems. The Montreal Protocol specifies that production of CH<sub>3</sub>Br in developed countries be reduced by 50% from 1991 levels by 2001, and recent estimates of production are consistent with this reduction.

The major source of PFCs is the aluminum industry, CF<sub>4</sub> and C<sub>2</sub>F<sub>6</sub> being released as by-products during the electrolytic conversion of aluminum oxide to aluminum. Annual CF<sub>4</sub> emissions

**Figure 1** Annual production of selected CFCs, HCFCs, and HFCs by companies reporting to AFEAS (Alternative Fluorocarbons Environmental Acceptability Study) over the period 1980–2001. The AFEAS data typically account for over 90% of total global production. (Data available at <http://www.afeas.org/>.)

of  $\sim 11 \text{ Gg year}^{-1}$  were estimated for the period 1992–98, 40% lower than the equivalent estimates for 1978–90. PFCs are also used in the semiconductor industry for processes such as plasma etching. A natural source of  $\text{CF}_4$  from fluorite minerals has also been identified, which may account for  $\sim 50\%$  of the current atmospheric burden.  $\text{SF}_6$  is mostly used as an insulating fluid in electrical switchgear and as a blanket gas in magnesium production.

## Atmospheric Loss Processes and Lifetimes

The primary atmospheric removal processes for halocarbons are photolysis and reaction with tropospheric hydroxyl radicals (OH). For the fully halogenated CFCs and halons, photolysis is the only important sink and their atmospheric lifetimes are dependent on their absorption cross-sections, the solar flux, and the surface to stratosphere transport time. As a general rule, the greater the number of Cl, Br, or I atoms on any one carbon atom, the larger the cross-section and the shorter the lifetime. For example, the lifetimes of  $\text{CClF}_3$  (CFC-113),  $\text{CCl}_2\text{F}_2$

(CFC-12), and  $\text{CCl}_3\text{F}$  (CFC-11) are 640, 100, and 45 years, respectively. The type of halogen atom is also important, as this influences not only the atmospheric lifetime but also the region in the atmosphere where photolysis can occur. For example, bromine-containing halons such as  $\text{CBrClF}_2$  (H-1211) typically absorb at longer wavelengths than their CFC analogs ( $\text{CCl}_2\text{F}_2$ ) and are, therefore, photolyzed at lower altitudes. This has important consequences for ozone chemistry, as bromine source gases tend to release their Br atoms in the lower stratosphere where ozone concentrations are greatest. Iodocarbons are readily photolyzed at wavelengths that penetrate to the surface and, consequently, their lifetimes are comparatively short, ranging from a few hours ( $\text{CH}_2\text{ClI}$ ) to several days ( $\text{CH}_3\text{I}$ ).

For halocarbons that contain a carbon–hydrogen bond, reaction with tropospheric OH becomes important and their atmospheric lifetimes become dependent on the relative rates of the OH–halocarbon reaction and the global concentration and distribution of OH. Compounds for which OH reaction is the predominant sink include HCFCs, HFCs,  $\text{CH}_3\text{CCl}_3$ ,  $\text{CH}_3\text{Cl}$ , and  $\text{CH}_3\text{Br}$ .

PFCs and  $\text{SF}_6$  are highly resistant to normal atmospheric removal processes and will persist in

the atmosphere for many thousands of years. The lifetime of  $\text{CF}_4$ , for example, has been estimated at 50 000 years. Minor loss process may include high-temperature combustion in power plants and incinerators and reactions with free electrons or  $\text{O}^+$  in the upper atmosphere.

## Analytical Methods

### Atmospheric Sampling

Measurements of halocarbons in the atmosphere can either be made *in situ*, where an analytical instrument is operated in the field or, alternatively, air samples can be collected and returned to the laboratory for subsequent analysis. Advantages of *in situ* measurements include more frequent data collection, which can lead to a greater understanding of daily and seasonal variations, and problems associated with sample storage are avoided. On the other hand, sample collection enables measurements to be made from a much wider range of location, giving a broader picture of spatial distribution. Collected samples can also be analyzed using different instruments, increasing the number and type of compound measured, and can also be stored for future analysis.

Stainless-steel canisters are the preferred choice for air sample collection, although glass vessels, polytetrafluoroethylene bags, and chemical absorbents have also been used, depending on the type and concentration range of the target compound. The internal surfaces of stainless-steel canisters are normally treated to reduce the number of active adsorption sites, thereby increasing the stability of compounds during storage. Electropolishing using techniques such as the SUMMA process, in which a pure chrome–nickel oxide layer is coated on the inner metal surface, is most common although canisters with a fused silica coating have recently become available, which helps to improve the stability of certain species. Canisters are normally fitted with a noncontaminating stainless steel valve to allow for filling or venting of air, and are available in a variety of sizes ranging from 0.5 to 30 l. Before use they should be cleaned by evacuation and repeat flushing with zero air or nitrogen, preferably at elevated temperatures (100–150°C). Humidification of the cleaned cylinder can help the stability of certain compounds.

Canisters can be filled in a variety of ways, the simplest being to fill an evacuated canister to ambient pressure by opening the valve at the sampling location. Alternatively, they can be filled using a small, noncontaminating pump. The pump should be

clean, oil and grease free, and preferably constructed so that sampled air does not come into contact with plastic or rubber seals, a potential source of contamination. Metal bellows type pumps are often used which are capable of pumping to pressures of 3–4 bar, giving ~10 l of air in a 3 l canister. Air samples can also be collected cryogenically, by partially immersing an evacuated canister in liquid nitrogen and allowing air to be drawn in and condense. Cryogenic sampling is clean, as no pump is required, and is particularly useful for collecting large volumes of air, e.g., for use as long-term calibration standards.

The suitability of stainless-steel canisters for halocarbon measurements at sub-ppb levels is well documented. Although stability over extended periods of time has been shown for many species, including CFCs, halons, HCFCs, HFCs, and PFCs, it is normally advisable to analyze samples as soon as possible after collection to minimize the risk of sample degradation. Specific problems relating to the storage of certain compounds, notably  $\text{CCl}_4$ , have been reported and the storage of more reactive halocarbons such as  $\text{CH}_3\text{Br}$  and  $\text{CH}_3\text{I}$  is not always reliable. As a general rule, sample stability is improved when samples are collected wet (or the containers are prehumidified) and when the air is stored at higher pressures.

Aluminum cylinders have also been used for air sampling, and are particularly useful as long-term standards since they can be filled to much higher pressures. For halocarbon measurements the internal surface can be passivated to allow for optimum compound stability. Long-term storage (several years) of CFCs, HCFCs, and HFCs at ppt levels has been demonstrated in Aculife-treated cylinders, although the stability of more reactive halocarbons, such as  $\text{CH}_3\text{Cl}$  and  $\text{CH}_3\text{Br}$ , remains problematical. Unlike stainless-steel canisters, aluminum cylinders must be filled with dry air as water can damage the passivation treatment.

### Chromatographic Methods

Historically, atmospheric halocarbon measurements have been made primarily using gas chromatography with electron capture detection (GC-ECD). The ECD was invented during the 1960s and is particularly sensitive to halocarbons with multiple chlorine, bromine, and/or iodine atoms. In general, the response of an ECD increases with the number and type of halogen atoms present (i.e.,  $\text{F} < \text{Cl} < \text{Br} < \text{I}$ ). For example, an ECD is more sensitive to  $\text{CH}_3\text{I}$  than  $\text{CH}_3\text{Br}$ , and more sensitive to  $\text{CHCl}_3$  than  $\text{CH}_2\text{Cl}_2$ . The CFCs, which contain multiple chlorine atoms, are particularly suited to electron capture even at low

ppt levels. GC-ECD has also been used for chlorinated solvents, including  $\text{CH}_3\text{CCl}_3$  and  $\text{CCl}_4$ , various bromo- and iodo-carbons, and  $\text{SF}_6$ .

HCFCs and HFCs are more difficult to measure by conventional GC-ECD. HCFCs typically contain less chlorine than their CFC counterparts, whilst HFCs, being composed of only carbon, hydrogen, and fluorine, are largely insensitive to the ECD. It is possible to increase the sensitivity of an ECD to certain halocarbons by doping the nitrogen make-up gas with a small amount of oxygen, typically  $\sim 0.2\%$ . The increased response is thought to be due to oxygen ( $\text{O}_2^-$ ) serving as a catalyst for electron capture. Response factors can be further improved by careful choice of operating conditions, including the use of lower detector temperatures (typically  $250^\circ\text{C}$ ) and lower ECD standing currents. Compounds that show an enhanced response to oxygen-doped ECD include HCFC-22,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{Br}$ , and  $\text{CH}_2\text{Cl}_2$ . Disadvantages of oxygen doping include increased background noise and greater potential for coelutions.

A more popular, and sometimes necessary, alternative for the analysis of CFC replacements and other ECD-weak halocarbons is gas chromatography/mass spectrometry (GC-MS). The most common GC-MS systems utilize a quadrupole analyzer, although magnetic sector instruments have also been used, which are capable of operating at higher mass resolution and have lower detection limits (parts in  $10^{15}$ ). Both are scanning analyzers, where ions are detected sequentially with time. The advantages of a quadrupole include cost, ease of use, rapid scanning speeds, and the linear variation of ion count and quadrupole field voltage. However, they are only able to operate at low resolution and are typically several orders of magnitude less sensitive than the best sector instruments.

For rapid scanning of GC output and to maximize sensitivity, mass analyzers are normally operated in selected ion mode, where only a few pre-selected ions are monitored at any one time. Electron ionization at 70 eV is normal although increased response has been observed in some systems using helium carrier gas when operated at lower ionization energies (10–20 eV). There is a growing interest in the use of negative ion chemical ionization as this technique is very sensitive to certain halocarbons, notably those containing bromine or iodine.

GC-MS has a number of advantages over other GC techniques. The ability to identify a compound by its mass spectrum or by the coelution of specific ion fragments is preferable to relying on retention time analysis alone. MS detection can help in the identification of unknown compounds and also in the

detection and identification of coeluting species. Furthermore, where two compounds are shown to coelute, either or both can still be analyzed quantitatively with the use of single ion monitoring, provided they produce nonidentical ions. Another advantage of GC-MS is the wider variety of compounds that can be measured with just one instrument. For atmospheric halocarbon measurements, GC-MS enables the detection of many more compounds, including HCFCs, HFCs, and PFCs. Finally, in the case of magnetic sector instruments, the ultimate detection limit of parts in  $10^{15}$  or better is probably two orders of magnitude better than an ECD.

Due to their superior resolving power and suitability for use with GC-MS (lower flow rates, reduced chemical bleed), capillary columns are gradually replacing packed columns as the column of choice for halocarbon analysis. Low polarity methyl and methyl/phenyl polysiloxane columns are widely used and suitable for all but the most volatile species. Column lengths typically range from 30 to 100 m and internal diameters from 0.25 to 0.53 mm ( $\leq 0.32$  mm for GC-MS). Alumina-PLOT columns offer excellent separation of the fully halogenated CFCs, PFCs, and halons, as well as HFCs, but are very sensitive to water and cannot be used for many hydrogenated compounds containing chlorine, bromine, or iodine as these can decompose on the column. Other columns widely used include various other PLOT columns (Poraplot-Q, GS-Q) and the 624-type columns, designed for the analysis of volatile pollutants using US-EPA methods.

With packed column GC-ECD it is possible to measure the major CFCs (11, 12, 113) as well as several chlorinated solvents ( $\text{CH}_3\text{CCl}_3$ ,  $\text{CCl}_4$ ) and  $\text{SF}_6$  in the background atmosphere by a simple loop injection of 1–10 ml of air. However, to measure a greater number of compounds and to be able to work with capillary columns and GC-MS it is necessary to preconcentrate samples before analysis. A variety of techniques have been developed to accomplish this and there are several systems available commercially. The general principal involves passing air through a trap, often held at subambient temperatures, so that the halocarbons and other compounds of interest are trapped, whilst the bulk of the air (mainly  $\text{N}_2$  and  $\text{O}_2$ ) passes through unretained. Typical volumes processed range from 100 to 2000 ml, actual volumes being determined by mass flow or pressure difference. Traps are normally made of stainless steel or glass and may be empty or packed with glass beads or chemical adsorbents such as Tenax or Carboxen. The most sophisticated traps may contain multiple adsorbents to allow for analysis of the widest possible range of compounds. To increase trapping

efficiency, traps are normally cooled to subambient temperatures using cryogenic fluids, recirculating refrigerants, or peltier-type coolers, the required temperature being dependent on the efficiency of the trapping material. Injection of the trapped sample onto the GC column is facilitated by rapid heating of the sample loop. When preconcentrating large volumes of air it is usually necessary to remove water vapor from the sample stream. Water can not only cause a blockage in the trap but can also affect chromatographic performance and detector response. If the dimensions of the trap are sufficiently large and care is taken with the desorption temperature, it is possible to retain water on the trap during desorption, particularly if there is a second prefocusing trap before injection onto the column. Otherwise water vapor can be removed using Nafion-type, semipermeable membranes or chemical dryers such as magnesium perchlorate or phosphorus pentoxide. Another potential interferent is CO<sub>2</sub>, particularly when analyzing very volatile halocarbons or trapping larger volumes of air.

### Calibration and Units

The most accurate gas-phase calibration standards are those made gravimetrically. Gravimetric standards are normally prepared in dry aluminum or humidified stainless-steel cylinders and typically consist of a small amount of pure material, gas or liquid, diluted with real air or synthetic air/nitrogen at high pressure. High-precision balances are necessary to determine the weight of raw material and sometimes that of the diluent gas. Commercial gravimetric standards for some halocarbons are available, although these are normally in the high ppb (parts per billion) range and have to be diluted further before analysis, either by static dilution into known volumes or by dynamic dilution with zero air or nitrogen.

Other calibration techniques include mixing a known volume of gas with nitrogen or air in a fixed volume container and the use of liquid standards, where analytes are purchased or prepared in a liquid matrix, such as methanol, and then diluted into the gas phase. These methods usually involve several dilution steps to generate standards in the ppt range. Permeation devices have also found limited use.

For atmospheric analysis, secondary or working standards are normally analyzed alongside real samples and are used to monitor daily or longer-term changes in instrument response. These standards are typically large-volume, high-pressure air samples, which are calibrated against primary standards before and after use. As both primary

and secondary standards are often used for many months or years, care has to be taken to monitor compound stability and to ensure continuity between different standards.

Atmospheric concentrations are normally expressed as mixing ratios, the preferred unit being dry air mole fraction, normally parts per trillion (10<sup>12</sup>), ppt, or pmol mol<sup>-1</sup>. For standards prepared volumetrically, corrections for nonideal behavior should be applied.

### Spectroscopic Methods

Halocarbon measurements in the atmosphere have also been made by remote sensing techniques, which negate the requirement for sample collection or preconcentration. Since many halocarbons have strong absorption bands in the 8–15 μm region, infrared spectroscopy has proved to be a valuable technique for the measurement of certain molecules including CFCs 11, 12, and 113, HCFC-22, CCl<sub>4</sub>, CF<sub>4</sub> and SF<sub>6</sub>. Most spectrometers in current use are rapid-scanning, high-resolution, Fourier-transform interferometers that use sunlight as the radiation source, i.e., the instrument records the difference between the true solar spectrum and the solar spectrum after passage through a portion of the atmosphere. Surface-based spectrometers are capable of quantifying total vertical column amounts, whilst balloon- or aircraft-borne instruments provide better spatial and vertical resolution. The ATMOS spectrometer (Atmospheric Trace Molecule Spectroscopy Experiment) has been flown several times on the space shuttle generating high-resolution (0.01 cm<sup>-1</sup>) absorption spectra of the atmosphere from space with a vertical resolution of ~2 km. Measurements have also been made from satellites.

### Global Halocarbon Monitoring

Halocarbon measurements have been made from a variety of platforms including ground-based sites, ships, aircraft, and balloons. There are several well-established global networks making regular, long-term measurements of certain species using *in situ*, canister, and remote sensing techniques. Canister samples are regularly collected from dedicated research aircraft, from commercial airliners, and even from balloon-borne samplers reaching altitudes of ~30 km. Lightweight, fast-response GC-ECD systems have also been flown on research aircraft and balloons, and the first flying GC-MS systems are being developed. As fast response times are desirable, airborne GCs are normally designed to analyze a limited number of compounds, typically two to three

compounds every 1–2 min. Chromatographic conditions such as column selection and pressure control are critical and systems normally use precolumns and/or back-flushing to prevent unwanted components from reaching the detector.

Several studies have reported halocarbon measurements in air trapped in polar firn (unconsolidated snow). Air pumped out of the firn at different depths is representative of a particular period of time, depending on diffusion rates within the snow. Firn can reach depths in excess of 100 m, and the oldest derived atmospheric records date back to the early twentieth century. These confirm that natural sources of CFCs, HCFCs, HFCs, halons, chlorinated solvents, and SF<sub>6</sub> are negligible or nonexistent. Halocarbons with significant preindustrial abundance include CF<sub>4</sub>, CH<sub>3</sub>Cl, and CH<sub>3</sub>Br.

## Atmospheric Abundance and Temporal Trends

Routine monitoring of the major CFCs, CH<sub>3</sub>CCl<sub>3</sub> and CCl<sub>4</sub> began in the late 1970s. Atmospheric mixing ratios increased steadily until the Montreal Protocol took effect in the early 1990s and growth rates began to slow. The global mean surface concentrations of CFC-11 and CFC-113 reached maxima of 275 and 85 ppt around 1993 and 1996, respectively, and have been declining slowly since. By 2000, the concentration of CFC-12 had reached 540 ppt, although its growth rate had fallen to just 2 ppt year<sup>-1</sup>, compared with 20 ppt year<sup>-1</sup> during the 1980s. With lifetimes ranging from 50 to 100 years, it will be several decades before CFC

concentrations decline substantially. In contrast, the atmospheric abundance of CH<sub>3</sub>CCl<sub>3</sub>, which has a relatively short lifetime (5 years), decreased from 130 ppt in 1992 to 45 ppt in 2000, a decline of over 60% (see Table 3).

Global atmospheric mixing ratios of HCFCs and HFCs continue to rise. Several compounds (HCFC-141b, HCFC-142b, HFC-134a) have increased rapidly from zero or near-zero levels in the late 1980s as they have found use as CFC replacements. Others, like HCFC-22 and HFC-23, have grown more steadily. However, with the exception of HCFC-22, which had reached 140 ppt by 2000, the concentrations of other HCFCs and HFCs were all below 20 ppt, still significantly lower than the major CFCs. A number of other CFC replacements have also been identified in the atmosphere, including HCFC-123, HCFC-124, HFC-125, HFC-143a, and HFC-152a. Atmospheric levels of these compounds are currently a few ppt or less, but may be expected to increase in coming years (see Figure 2).

The behavior of the CFCs has generally followed a predictable pattern with atmospheric growth rates declining as industrial production and emissions have decreased. CFC-12 is taking longer to stop as much of its use involved slow release applications such as refrigeration. The behavior of halons is different and atmospheric levels of H-1211 and H-1301 are still increasing despite having one of the earliest phase-out dates. The reason for this lies partly in the way halons were used. Compared to CFCs and CH<sub>3</sub>CCl<sub>3</sub>, a far greater proportion of total halon production is stored in existing equipment and forms part of a bank of unreleased material. Two other halons to be

**Table 3** 2000 surface mixing ratios and growth rates of the major atmospheric halocarbons

Formula	Common name	Mixing ratio 2000 (ppt)	Growth rate 2000 (ppt year <sup>-1</sup> )
CCl <sub>3</sub> F	CFC-11	260	-1.5
CCl <sub>2</sub> F <sub>2</sub>	CFC-12	540	2.0
CClF <sub>2</sub> CCl <sub>2</sub> F	CFC-113	82	-0.4
CBrF <sub>3</sub>	Halon-1301	2.5	0.07
CBrClF <sub>2</sub>	Halon-1211	4	0.12
CHClF <sub>2</sub>	HCFC-22	140	5.2
CH <sub>3</sub> CClF <sub>2</sub>	HCFC-142b	12	1.0
CH <sub>3</sub> CCl <sub>2</sub> F	HCFC-141b	13	1.8
CHF <sub>3</sub>	HFC-23	16	0.9

CCl <sub>4</sub>	Carbon tetrachloride	100	-1.0

Adapted from WMO (World Meteorological Organisation) (2003) *Scientific Assessment of Ozone Depletion: 2002*. Global Ozone Research and Monitoring Project, Report No. 47, Geneva.

**Figure 2** Southern hemispheric surface mixing ratios of selected halocarbons over the period 1978–2002. CFC,  $\text{CH}_3\text{CCl}_3$ , and  $\text{CCl}_4$  data are from the ALE/GAGE/AGAGE network (Prinn *et al.*, 2000, *J. Geophys. Res.*, 115: 17751–17792. <http://cdiac.ornl.gov/>). HCFC-22 data are from NOAA-CMDL (Montzka *et al.*, 1996, <http://www.cmdl.noaa.gov/hats/index.html>). Other HCFC, HFC, and halon data are updated from Oram *et al.* (1995, 1996, 1998) and Fraser *et al.* (1999).

detected in the background atmosphere are H-2402 and H-1202. Although global surface mixing ratios of individual halons were less than 5 ppt in 2000, total halon-derived bromine had risen to 8 ppt and was still increasing at  $0.2 \text{ ppt Br year}^{-1}$ . Firn studies suggest that  $\text{CH}_3\text{Br}$  was present at 5–6 ppt at the beginning of the twentieth century (prior to industrial use) and had risen to 10 ppt by the 1990s. However, recent measurements indicate that the abundance of  $\text{CH}_3\text{Br}$  may now be in decline.

A number of perfluorinated carbon and sulfur compounds have been detected in the background atmosphere, including  $\text{CF}_4$ ,  $\text{C}_2\text{F}_6$ ,  $\text{C}_3\text{F}_8$ ,  $\text{c-C}_4\text{F}_8$ ,  $\text{SF}_6$ , and  $\text{SF}_5\text{CF}_3$ . With the exception of  $\text{CF}_4$ , which is present at  $\sim 80 \text{ ppt}$ , atmospheric mixing ratios for individual compounds are currently less than 5 ppt, although all are increasing and could become important contributors to radiative forcing in the future.

## Introduction

Chromatography can be used to solve a very broad range of analytical problems. This versatility is reflected in the large number of chromatographic techniques that are successfully applied today. They can be classified according to a number of criteria, the most important of which is the type of mobile phase used. Subsequently the shape of the chromatographic bed and the properties of the stationary phase expand the possibilities offered by chromatography. Once a particular method is chosen, it is possible to influence the separation using programmed elution. Finally special techniques can be used to perform difficult analyses or to obtain short separation times. The individual methods are discussed in detail in

their respective articles, so here only a short introduction is given.

## Classification of Chromatographic Techniques

### The Type of Mobile Phase

Chromatographic techniques can be classified on the basis of a number of different criteria. Nevertheless, a logical hierarchy is given by first specifying the type of mobile phase, second the shape of the chromatographic bed and third the type of stationary phase. In **Table 1** the chromatographic methods are listed according to this scheme. The type of mobile phase is the most important criterion because it determines the class of samples that can be analyzed with one of the associated techniques. (From a theoretical point of view, each type of mobile phase also governs a certain range of diffusion coefficients, which determines and limits the speed of analysis and the efficiency of the method.) Therefore a distinction can be made between gas, supercritical fluid, and liquid chromatography (GC, SFC, and LC, respectively).

## Introduction

Chromatography can be used to solve a very broad range of analytical problems. This versatility is reflected in the large number of chromatographic techniques that are successfully applied today. They can be classified according to a number of criteria, the most important of which is the type of mobile phase used. Subsequently the shape of the chromatographic bed and the properties of the stationary phase expand the possibilities offered by chromatography. Once a particular method is chosen, it is possible to influence the separation using programmed elution. Finally special techniques can be used to perform difficult analyses or to obtain short separation times. The individual methods are discussed in detail in

their respective articles, so here only a short introduction is given.

## Classification of Chromatographic Techniques

### The Type of Mobile Phase

Chromatographic techniques can be classified on the basis of a number of different criteria. Nevertheless, a logical hierarchy is given by first specifying the type of mobile phase, second the shape of the chromatographic bed and third the type of stationary phase. In **Table 1** the chromatographic methods are listed according to this scheme. The type of mobile phase is the most important criterion because it determines the class of samples that can be analyzed with one of the associated techniques. (From a theoretical point of view, each type of mobile phase also governs a certain range of diffusion coefficients, which determines and limits the speed of analysis and the efficiency of the method.) Therefore a distinction can be made between gas, supercritical fluid, and liquid chromatography (GC, SFC, and LC, respectively).

**Table 1** Classification of chromatographic methods

Type of mobile phase	Gas	Supercritical fluid	Liquid
Shape of chromatographic bed	Column	Column	Column (Open tubular) Packed
Type of stationary phase	Open tubular: Liquid, cross-linked liquid Packed: Liquid, Solid	Open tubular: Cross-linked liquid Packed: Solid	Column (Packed): Solid Paper: Liquid Thin-layer: Solid
Method	Gas-liquid chromatography Gas-solid chromatography	Capillary supercritical fluid chromatography Packed column supercritical fluid chromatography	Column liquid chromatography Paper chromatography Thin-layer chromatography
Abbreviation	GC, GLC GC, GSC	SFC	LC HPLC <sup>a</sup> PC TLC HPTLC <sup>b</sup>
Type of method	Adsorption, molecular sieve, porous polymer	Adsorption, bonded phase	Adsorption, reversed phase, bonded phase, ion exchange, affinity, size exclusion

<sup>a</sup>High-performance liquid chromatography.

<sup>b</sup>High-performance thin-layer chromatography.

The high-performance methods use stationary phases of very small particle diameter.

SFC is less important than GC or LC. In many cases, it is not difficult to choose between the latter two methods: the prerequisite for GC is that the analyte is volatile and thermally stable (although derivatization in order to obtain these properties is possible in many cases).

### The Shape of the Chromatographic Bed

If the mobile phase is a gas or a supercritical fluid, it is necessary to let it flow through a tube, a so-called column, that contains the stationary phase. In the case of liquid chromatography one can choose between a column or planar geometry because the mobile phase can move through a sheet of paper or a thin layer by capillary action. If a column is used, the mobile phase is forced through it by pressure generated by a pump or by a gas stored in a pressurized cylinder. (As a preparative laboratory technique, liquid chromatography is also performed in columns packed with coarse stationary phases; in this case simple hydrostatic pressure may be sufficient.)

The column can be an open capillary or a packed tube. In the first case the mobile phase is coated as a thin film on the inner wall of the capillary. If the mobile phase has a certain solvating power, as in SFC, it is necessary to cross-link this liquid film, whereas in GC linear polymers are used in many cases because the usual carrier gases, helium and hydrogen, cannot dissolve any stationary phase. (Owing to problems with manufacturing and

**Figure 1** Three possibilities for creating a chromatographic bed: (A) packed column, (B) open capillary, and (C) plane. The third technique can only be used with a liquid mobile phase; here a thin-layer plate is drawn but the plane can also consist of a sheet of paper. In all three cases the stationary phase is shown in gray. The particles of the packed column can be round, as in the figure, or irregular.

instrumentation, liquid chromatography with open capillaries is only of theoretical interest.) If the column contains packing, many possibilities are offered by contemporary technology. The stationary phase can be an inorganic adsorbent, a cross-linked and thereby rigid organic polymer, an inorganic or organic material with chemically modified surface, or even a liquid film coated on a granular carrier material.

Figure 1 shows the three possibilities: packed column, open capillary, and plane.

### Terminology of the Methods

Taking the type of chromatographic bed and stationary phase into account, GC, SFC, and LC can

now be subdivided, although the usual terms do not follow the same criteria in all cases. **Table 1** uses the expressions gas–liquid, gas–solid, capillary supercritical fluid, packed-column supercritical fluid, column liquid, paper, and thin-layer chromatography. The following abbreviations are used: GLC, GSC, but in most cases the type of stationary phase is omitted and both techniques are termed GC; SFC; LC (usually only used for column techniques, although thin-layer and paper chromatography are also ‘LC’); PC (sometimes also used for ‘preparative chromatography’); and TLC. For LC and TLC, which both use a granular stationary phase, a special term was introduced to distinguish the more recent instrumental methods based on very fine stationary phases from the classical ones: HPLC and HPTLC where HP is for ‘high performance’. Here the particle diameter is not larger than  $\sim 10\ \mu\text{m}$ , which is the key to obtaining high plate numbers per unit length.

Especially in LC, and also in other fields, it is usual to distinguish in more detail between very different types of method. This will be discussed below.

### Comparison of the Methods

**Table 2** lists some characteristic features of GC, SFC, and LC. In most cases GC is used as open-tubular GLC, and LC is performed in packed columns. As can be seen from the physical parameters of density, viscosity, and diffusion coefficient, SFC lies between GC and LC and it is no surprise that it can be used equally well with open capillaries and packed columns. The values in the table are to some extent arbitrary but are typical. The values of the three basic physical parameters are not only of theoretical interest but are linked directly to some of the main

properties of the methods: the density governs the solvating power of the mobile phase and thereby determines whether the separation can be influenced by a particular choice of eluent; the viscosity influences the pressure needed to force the mobile phase through the chromatographic bed and sets the upper limit of the solute diffusion coefficient. This latter should be high because low diffusivity means slow mass transfer and therefore slow chromatography. If the sample diffusion coefficient is low, it is necessary to keep low the characteristic chromatographic dimension, i.e., the capillary or particle diameter. Therefore, LC with  $5\ \mu\text{m}$  particles is more efficient than with a  $100\ \mu\text{m}$  packing.

Practical aspects of the three methods are listed under Variables and Sample Prerequisites at the end of **Table 2**.

### Gas Chromatography

If the mobile phase is a gas, the sample needs to be volatile. Its boiling point at atmospheric pressure should not be higher than  $\sim 360^\circ\text{C}$ . If the temperature of the GC column or capillary is adequate, the sample molecules will be transported by the gas owing to their volatility. Retention is governed by both vapor pressure and affinity to the stationary phase of a given compound. The gaseous mobile phase has no direct influence on the separation. GC can be a simple and rapid technique and is the method of choice for the investigation of volatile and even very complex samples. An example is given in **Figure 2**.

The most frequently used mobile phases for GC are hydrogen and helium. The lower the molecular

Sample prerequisites	Volatility Thermal stability	Solubility (Thermal stability)	Solubility

<sup>a</sup>For open tubular and packed columns, respectively.

<sup>b</sup>In SFC the pressure drop over the column can be chosen.

**Figure 2** Gas chromatographic separation of hydrocarbons found in an urban air sample. Open capillary, 0.32 mm i.d.  $\times$  60 m length; stationary phase, DB-1 (dimethyl polysiloxane); film thickness, 0.25  $\mu\text{m}$ ; carrier gas, helium; temperature programme, 5°C isothermal for 3 min, 5–50°C at a rate of 3°C min<sup>-1</sup>, 50–220°C at a rate of 5°C min<sup>-1</sup>; detector, flame ionization. With this method, a total of 142 hydrocarbons could be separated and identified; 128 of them were found in the urban air sample. (After Ciccioli P, Cecinato A, Brancaleoni E, Frattoni M, and Liberti A (1992) Use of carbon adsorption traps combined with high resolution GC–MS for the analysis of polar and nonpolar C4–C14 hydrocarbons involved in photochemical smog formation. *Journal of High Resolution Chromatography* 15: 75.)

mass of a gas, the lower its own diffusivity as well as the diffusivity of the sample molecules and the faster the chromatography. Therefore, hydrogen would be the favored carrier gas but it is often barred on safety grounds. Sometimes nitrogen is used because it is cheap but this can only be recommended for simple analytical problems because the separation performance is poorer than with gases of low molecular mass. The fact that some detectors demand the use of a certain gas must also be taken into consideration.

A typical stationary phase for GC is a viscous liquid with low vapor pressure (at the temperature required for a given range of application). The two most important types of stationary phases are silicones and polyglycols; their structures are given in Table 3. The silicones especially can be substantially chemically modified in order to obtain a wide range of polarities and specialized functionalities (including chiral groups). The stationary phase is coated as a thin film (typically 0.25  $\mu\text{m}$ ) on the inner wall of the open capillary or on the surface of a granular, porous, inert packing material, in this case called a solid support. For special types of analyses the stationary phase is not a liquid but a porous–solid packing. Adsorbents (silica), molecular sieves and porous polymers are used for the GSC of highly volatile samples such as mixtures of permanent gases or low-molecular-mass hydrocarbons.

In GC, the eluted compounds are most often detected with a flame-type detector that generates ions, the so-called flame ionization detector, FID; for special purposes nitrogen- and phosphorus-sensitive FIDs, electron capture, or thermal conductive detectors and mass spectrometers are used.

If a sample is not volatile, several derivatization techniques are known that allow reduction in the boiling points of certain classes of compounds.

Alcohols, amines, amino acids, carboxylic acids, carbohydrates, and steroids can be trimethylsilylated; amines, phenols, carbohydrates, and steroids can be acylated with trifluoroacetic acid or a higher homolog; carbonic acids and phenols can be alkylated.

## Liquid Chromatography

Liquid chromatography has a number of different configurations with regard to technical (instrumental) as well as separation modes. Paper, thin-layer, and classical column techniques all belong to liquid chromatography and the ‘high performance’ technique especially (though to a lesser extent the other methods also) offers a great variety of separation principles.

### Paper Chromatography

The simplest and cheapest technique is paper chromatography, where the chromatographic bed consists of a sheet of paper, i.e., cellulose. The stationary phase consists of water adsorbed to the cellulose as well as of the polymer itself, although ion exchange and complexation processes may play an important role. The sample solution is applied as a spot near one end of the paper. A few centimeters of the sheet are dipped into the mobile phase which then ascends (or descends, as descending mode is also possible) into the stationary phase. When the mobile phase has almost reached the other end of the sheet the paper is removed from the developing tank and dried. If the analytes are not visible because they are not colored, the sheet is treated with a reagent to visualize the spots.

**Table 3** Important stationary phases for GLC and (HP)LC

GC		
Silicones	$\left( \begin{array}{c} \text{R} \\   \\ \text{—Si—O—} \\   \\ \text{R}' \end{array} \right)_n$	With the proper choice of R and R' a wide range of polarities and special functionalities is available
Polyglycols	$\text{—(O—CH}_2\text{—CH}_2\text{)}_n\text{—OH}$	Polar stationary phase: $n$ ranges from 4 to 800
LC		
Silica	$\begin{array}{c}   \\ \text{(SiO}_2\text{)}_n\text{—Si—OH} \\   \end{array}$	Three-dimensional network
Octadecyl silica	$\begin{array}{c}   \\ \text{(SiO}_2\text{)}_n\text{—Si—C}_{18}\text{H}_{37} \\   \end{array}$	} Reversed phases
Octyl silica	$\begin{array}{c}   \\ \text{(SiO}_2\text{)}_n\text{—Si—C}_8\text{H}_{17} \\   \end{array}$	
Diol silica	$\begin{array}{c}   \\ \text{—(SiO}_2\text{)}_n\text{—Si—CH}_2\text{—CHOH—CH}_2\text{OH} \\   \end{array}$	} Polar bonded phases
Nitrile silica	$\begin{array}{c}   \\ \text{—(SiO}_2\text{)}_n\text{—Si—CH}_2\text{—CH}_2\text{—CN} \\   \end{array}$	
Amino silica	$\begin{array}{c}   \\ \text{—(SiO}_2\text{)}_n\text{—Si—CH}_2\text{—CH}_2\text{—NH}_2 \\   \end{array}$	
Polystyrene	$\begin{array}{c} \text{—(CH—CH}_2\text{)}_n\text{—} \\   \\ \text{C}_6\text{H}_5 \end{array}$	Three-dimensional network due to cross-linking with divinylbenzene
Strong cation exchanger	• $\text{—SO}_3^-\text{H}^+$	} • Can be silica or polystyrene
Weak cation exchanger	• $\text{—COO}^-\text{H}^+$	
Strong anion exchanger	• $\text{—NR}_3^+\text{OH}^-$	
Weak anion exchanger	• $\text{—NH}_3^+\text{OH}^-$	

### Thin-Layer Chromatography

Thin-layer chromatography is more versatile than paper chromatography since a number of different stationary phases are available such as silica, derivatized silica, or cellulose (the analogue to paper); also, developing times are much shorter. An immense number of spray reagents have been published that allow detection of any type of analyte. HPTLC is the 'high-performance' version of TLC and uses 10  $\mu\text{m}$  or 5  $\mu\text{m}$  stationary phase particles. The separation performance of these plates is higher, but to take full advantage it is necessary to use instrumentation for sample application, development, and detection. As an example of TLC, Figure 3 presents the separation of ten rare earths.

### Liquid Chromatography

Whereas chromatography in open columns is mainly used for preparative purposes, the analytical technique

is LC using microparticulate packings. Under these circumstances it is necessary to use a pump for mobile phase transport and a detector for the observation of the fractions (usually the concentration of the analytes in the eluate is low), e.g. UV absorbance, fluorescence, refractive index, or electrochemical detectors according to the properties of the analytes. It is also possible to derivatize the sample prior to or after the separation. Precolumn derivatization can be performed offline or online; postcolumn derivatization is usually carried out online. An example of LC is given in Figure 4, which shows the separation of the three stereoisomers of mivacurium, a neuromuscular blocking agent, in a plasma extract.

### Liquid Chromatographic Separation Principles

Liquid chromatography can be performed in a variety of modes; the most important ones are

**Figure 3** High-performance thin-layer chromatographic separation of ten rare earths (as nitrates). Sample, 1  $\mu\text{g}$  each of rare earth; layer, silica, impregnated with ammonium nitrate prior to the separation; mobile phase, 4-methyl-2-pentanone/tetrahydrofuran/nitric acid/2-ethylhexylphosphonic acid mono-2-ethyl hexylester 3:1.5:0.46:0.46; developing distance, 5 cm; detection reagent, (1) spray of saturated alizarin solution in ethanol, (2) ammonia vapour, (3) gentle heating. (After Wang QS and Fan DP (1991) *Journal of Chromatography* 587: 359.)

presented briefly. Schematic drawings are shown in **Figure 5**, and **Table 3** also lists some stationary phases used in LC.

**Adsorption chromatography** The stationary phase is a polar adsorbent, in most cases silica. The mobile phase is nonpolar (usually a solvent with polarity within the range from hexane to esters). It competes with the sample molecules for adsorption at the active sites of the stationary phase. Nonpolar compounds are eluted first, followed by solutes of increasing polarity. Steric properties of the sample compounds can play an important role and therefore adsorption chromatography is the method of choice for the separation of many classes of isomers.

**Reversed-phase chromatography** The stationary phase here is nonpolar; in most cases it is derivatized silica that carries  $\text{C}_{18}$  (i.e.,  $\text{C}_{18}\text{H}_{37}$ ) or  $\text{C}_8$  (i.e.,  $\text{C}_8\text{H}_{17}$ ) groups. The mobile phase is polar, in most cases a mixture of water (or buffer solution) with methanol, acetonitrile, or tetrahydrofuran. Such an eluent cannot wet the surface of the stationary phase and the solutes are retained owing to an energy gain

that comes from the decrease in contact area between the two phases as long as the sample molecules adhere to the hydrocarbon chains. Polar analytes are eluted first and homologs will be retained more strongly the longer their chain length. Ionic compounds can be separated on reversed phases if a neutral ion-pair is formed by the addition of a counter-ion to the eluent. This was carried out in the separation shown in **Figure 4**: mivacurium is a quaternary amine, and therefore a sulfonic acid was added as an agent to mask its charge.

**Other bonded phases on silica (not illustrated in Figure 5)** Besides the nonpolar hydrocarbons, other functional groups can also be bonded to silica. Important stationary phases are diol, nitrile, amino (see **Table 3**), and a great number of special functionalities including chiral groups. The retention mechanisms are as variable as the stationary phases and are not known in some cases.

**Ion exchange chromatography** Ion exchange groups can be bonded to silica or to polystyrene. ‘Classical’ ion exchange is based on ionic equilibria between solute, buffer and stationary phase ions and counter-ions. Besides this ion exclusion mechanisms can also be utilized and special types of ion exchangers have been developed for the separation of the ions of strong acids and bases.

**Size exclusion chromatography** If the mobile phase has a good affinity for both the sample molecules and the stationary phase and if the latter has a well-defined pore structure, such a chromatographic system will separate the solutes according to their size. They will not be retained by the column packing but will enter the pores where the mobile phase is stagnant. Large molecules can utilize a smaller fraction of the pore volume than small ones and will be eluted earlier. Molecules that are too large to enter the pores are excluded and will appear as the first fraction at the column end.

**Affinity chromatography** The stationary-phase matrix can be loaded with chemically bonded, biologically active groups such as enzymes or antibodies. If a complex sample is injected into an affinity column, only those molecules will be retained that bind to the ligands; in the cases mentioned above these will be substrates or antigens. All other compounds will be swept away by the mobile phase. Afterwards the retained molecules can be eluted by switching to a specially designed mobile phase (e.g., change of pH or ionic strength). Affinity chromatography is a

**Figure 4** Liquid chromatographic separation of mivacurium stereoisomers in human plasma extract. The drug is a mixture of three isomers; the structure is drawn without stereochemical preference. Column, 4.6 mm i.d.  $\times$  12.5 cm length; stationary phase, LiChrospher 60 RP (reversed-phase) select B, 5  $\mu$ m; mobile phase, acetonitrile/water 40:60 with 0.005 mol l<sup>-1</sup> octanesulfonic acid (as ion-pair reagent), 1 ml min<sup>-1</sup>; detector, fluorescence 202/320 nm. Peaks: (1) is the *trans-trans* isomer (1*R*, 1'*R*, 2*S*, 2'*S*); (2) is the *cis-trans* isomer (1*R*, 1'*R*, 2*R*, 2'*S*); (3) is the *cis-cis* isomer (1*R*, 1'*R*, 2*R*, 2'*R*); (4) is the internal standard, the *trans-trans* analog of mivacurium with a benzene ring instead of the double bond in the middle of the molecule. (After Brown AR, James CD, Welch RM, and Harrelson JC (1992) Stereoselective HPLC assay with fluorometric detection for the isomers of mivacurium in human plasma. *Journal of Chromatography* 578: 302.)

highly selective method and works by an 'on-off switching' mechanism.

## Supercritical Fluid Chromatography

The phase diagram of a pure compound shows not only regions of the solid, liquid, and gaseous states, the equilibrium lines and the triple point, but also the critical point. If pressure and temperature exceed the critical values, the compound will be neither a liquid nor a gas, nor will the two phases coexist, but a supercritical fluid exists. This phase is denser and more viscous than a gas without attaining the properties of a liquid as shown in Table 2. The advantage of SFC over LC lies in the higher diffusion coefficient, which allows faster separations; in comparison to GC the mobile phase has a large solvating power and thus influences selectivity.

In most SFC separations carbon dioxide is used as the mobile phase; often a modifier (of polarity) such as methanol, other alcohols or water is added. The critical data for CO<sub>2</sub> are 31.3°C and 72.9 bar, values that can easily be handled by instrumental chromatography. To keep the column outlet under critical conditions, a restrictor (a device with a high

resistance to the eluent flow) needs to be installed after or at the outlet of the column.

Owing to its intermediate position between GC and LC, SFC can be performed equally well in open capillaries and packed columns. The separation can be influenced by the type of stationary phase and of modifier, by pressure, pressure drop, and temperature. In contrast to GC, SFC can also be used for the separation of nonvolatile or thermally labile compounds (although some temperature compatibility is necessary). The separation of enantiomers on chiral stationary phases can be very attractive because the temperature is lower than in GC, which increases the separation factors. SFC is an alternative to normal-phase LC because it is fast and carbon dioxide is ecologically sound. An example of an SFC separation can be found in the previous article, Principles, where Figure 2 shows the separation of orange oil components.

## Special Chromatographic Techniques

### Preparative Methods

Chromatography can equally well be used for analytical and preparative purposes. 'Preparative' is not

**Figure 5** Separation principles of liquid chromatography. (A) Adsorption chromatography: the adsorptive sites of the stationary phase are symbolized by A; the solute molecules interact with their polar groups X or Y; the mobile phase drawn is hexane, which can also interact weakly with A. (B) Reversed-phase chromatography: the solute molecules interact via their nonpolar groups with the nonpolar stationary phase. (C) Ion-exchange chromatography: a styrene-divinylbenzene type cation exchanger is shown; sample ions  $S^+$  and buffer cations  $K^+$  compete for interaction with the exchange sites. (D) Size exclusion chromatography: sample molecules can occupy the pore volume according to their size, therefore the macromolecule will spend less time in the pores and elute first. (E) Affinity chromatography: only certain sample molecules can fit to the ligands of the stationary phase, the others are washed out.

reserved to the fractionation of large samples, but indicates that the separated compounds are collected and used for a subsequent purpose: identification or structure elucidation, chemical modification by synthetic methods, use as a reference material, determination of chemical or biological properties, or for sale. If only small amounts of material are needed, the only difference from analytical chromatography lies in the use of a fraction collector; for routine separations it should be computer controlled.

If the sample size is increased, the shape of the peaks changes to rectangular (in the case of volume overload) or triangular (with mass overload); mixed forms and distorted peak shapes are also observed. Displacement effects can occur where a compound is 'pushed' and concentrated by a following one that has a stronger affinity to the stationary phase.

If large samples need to be separated, the diameter, and also often the length, of the column are increased. (Obviously, open capillaries cannot be used for this purpose.) Preparative GC is an attractive approach (though the fraction collector needs to be cooled) but few commercial instruments are available. Preparative LC is the most important technique in organic synthesis, biochemical research, downstream processing in biotechnology, and for the commercial preparation of certain chemicals or drugs.

### Programmed Elution

In a complex sample the individual analytes often have very different retention factors in a given chromatographic system. It is therefore not possible to

separate and elute them efficiently without changing the properties of the system, i.e. under so-called isothermal (GC) or isocratic (LC) conditions. In this case a GC separation is started at relatively low temperature, an LC separation at low eluting power of the mobile phase. Subsequently the temperature or mobile phase strength is increased in order to elute compounds that were strongly retained under the initial conditions. In GC this technique is called a temperature program (see **Figure 2**); the corresponding LC term is gradient elution. Note that in normal-phase LC the polarity of the mobile phase needs to be increased (however, gradient elution on silica is almost never performed because steep gradients are not possible and it takes a long time to re-equilibrate the column after the separation), whereas in reversed-phase LC the eluent polarity is decreased. A gradient from 10 to 100% acetonitrile in water can separate a very broad range of compounds on a reversed-phase column; pH or ionic strength gradients are also possible. In SFC, mobile phase, pressure, and temperature gradients are of equal importance.

### Column Switching

An alternative to programmed elution can be the coupling of two (or even more) columns with different stationary phases. This technique is known as multidimensional chromatography. The first column, for example, will separate the sample according to polarity groups. Then selected fractions are switched online to the second column, where the fine separation into chemically pure compounds takes place.

It is even possible to couple LC and GC; here, LC plays the role of a sample preparation technique that eliminates compounds that would affect the gas chromatographic separation. Because GC cannot tolerate high volumes of liquid, it is necessary to use narrow-bore LC columns, to split the eluate, or to use a special interface that eliminates most of the liquid.

### Special GC Techniques

**Headspace analysis** For the investigation of the volatile ingredients of complex mixtures, e.g., of olfactory principles, the sample is stored in a closed vial and perhaps gently heated. A portion of the vapor that fills the space over the solid or liquid sample is collected by a syringe and injected into the gas chromatograph. To obtain reproducible results it is necessary to control storage temperature and time strictly.

**Thermal desorption** Volatile compounds in gases such as pollutants in air can be trapped in a small adsorption tube, either by pumping the gas through or by passive diffusion. The packing in the trap can be chosen from a wide variety of adsorbents (molecular sieves, graphitized carbon blacks, organic polymers). After sample collection the adsorption tube is rapidly heated in a stream of purge gas which transports the released analytes to the GC column where the separation runs.

**Pyrolysis chromatography** For the GC analysis of high-molecular-mass samples such as plastics or wood, the sample can be pyrolyzed (heated until breakdown into smaller molecules occurs) online prior to injection. A 'fingerprint' of the material is obtained that can be used for quality control or identification purposes.

### Introduction

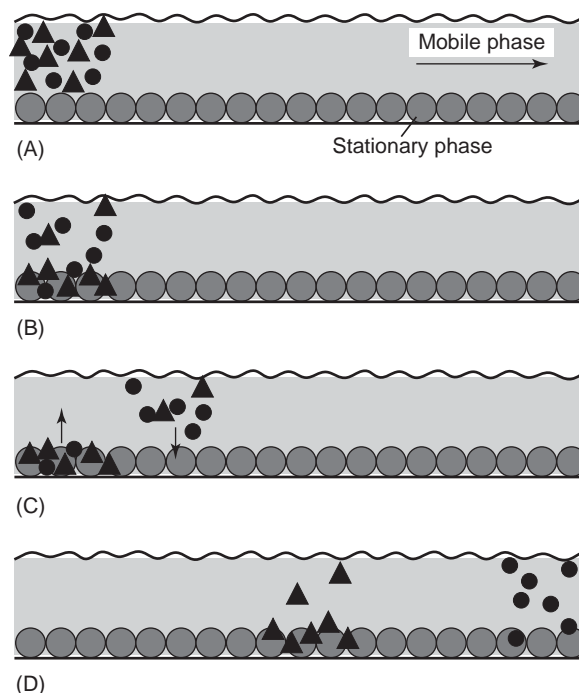

Chromatography is one of the most important analytical techniques. It allows the separation and subsequently the qualitative and quantitative analysis of complex mixtures, as long as the samples are volatile or soluble in a suitable solvent. Since chromatography is based on the partition of the sample components between two phases, one stationary and one moving, it is necessary to distinguish between gas, liquid, and supercritical fluid chromatography, according to the type of mobile phase used. Chromatography is versatile and can be highly efficient; full automation is possible. Some basic principles of its theory are presented here as knowledge of the underlying phenomena is necessary to take real advantage of all the possibilities offered by chromatographic techniques.

### The Chromatographic Process

In order to obtain a chromatographic separation, two phases are needed – a moving or mobile phase and a fixed or stationary phase. The stationary phase can be either a solid or a liquid, the mobile phase is a liquid, a gas, or a supercritical fluid. Both phases must be able to interact physically or chemically with the sample molecules; chromatography is based on transport, solvation, and ‘adsorption’ (in a very broad sense) phenomena. When the mobile phase is flowing through or over the stationary phase the analytes in the sample mixture undergo characteristic partition between the two phases. The mobile phase transports, the stationary phase retains. A mixture can be separated if its compounds are retained to varying degrees.

Figure 1 is a simple representation of the process. In (A) a mixture of seven molecules each of ● and ▲ is introduced into the chromatographic system. In (B) they are distributed between the upper mobile and lower stationary phase, and in (C) the mobile phase has transported the dissolved molecules over a small distance: new equilibria between the phases are established. When this process has been repeated many times, as in (D), the compounds ● and ▲ are separated because their preference for one of the two phases differs strongly.

In practice, chromatography takes place on a plane or in a tube. The plane can be a sheet of paper (paper

### Introduction

Chromatography is one of the most important analytical techniques. It allows the separation and subsequently the qualitative and quantitative analysis of complex mixtures, as long as the samples are volatile or soluble in a suitable solvent. Since chromatography is based on the partition of the sample components between two phases, one stationary and one moving, it is necessary to distinguish between gas, liquid, and supercritical fluid chromatography, according to the type of mobile phase used. Chromatography is versatile and can be highly efficient; full automation is possible. Some basic principles of its theory are presented here as knowledge of the underlying phenomena is necessary to take real advantage of all the possibilities offered by chromatographic techniques.

### The Chromatographic Process

In order to obtain a chromatographic separation, two phases are needed – a moving or mobile phase and a fixed or stationary phase. The stationary phase can be either a solid or a liquid, the mobile phase is a liquid, a gas, or a supercritical fluid. Both phases must be able to interact physically or chemically with the sample molecules; chromatography is based on transport, solvation, and ‘adsorption’ (in a very broad sense) phenomena. When the mobile phase is flowing through or over the stationary phase the analytes in the sample mixture undergo characteristic partition between the two phases. The mobile phase transports, the stationary phase retains. A mixture can be separated if its compounds are retained to varying degrees.

Figure 1 is a simple representation of the process. In (A) a mixture of seven molecules each of ● and ▲ is introduced into the chromatographic system. In (B) they are distributed between the upper mobile and lower stationary phase, and in (C) the mobile phase has transported the dissolved molecules over a small distance: new equilibria between the phases are established. When this process has been repeated many times, as in (D), the compounds ● and ▲ are separated because their preference for one of the two phases differs strongly.

In practice, chromatography takes place on a plane or in a tube. The plane can be a sheet of paper (paper

**Figure 1** Schematic representation of the process of a chromatographic separation. (A) Sample injection; (B) partition between the two phases; (C) progression of the mobile phase and new equilibrium; and (D) separation of the two compounds after a number of partition processes.

chromatography), or an adsorbent that is fixed onto a sheet of aluminum or glass (thin-layer chromatography); the tube can be an open capillary with the stationary phase coated on the inner wall (open-tubular chromatography) or a packed tube (packed-column chromatography). This is explained in more detail in the following article.

Two important aspects of **Figure 1** should be noted:

1. The degree of preference of compound  $x$  for one of the phases is expressed by the partition coefficient  $K$ , also called distribution constant.

$$K_x = \frac{c_{\text{stat}}}{c_{\text{mob}}} \quad [1]$$

where  $c$  is the concentration (strictly speaking, activity) of the compound in the mobile and stationary phase, respectively, at equilibrium.

In **Figure 1**,  $K_{\blacktriangle}$  is  $5/2 = 2.5$ ,  $K_{\bullet}$  is  $2/5 = 0.4$ . If  $K = \infty$  the compound is totally adsorbed by the stationary phase and will not be transported through the chromatographic bed. If  $K = 0$  no retention takes place and the residence time in the column will be minimal.

2. The chromatographic bed seems to consist of small, discrete units that correspond, in this case, to approximately three particle diameters of the stationary phase, and the mobile phase is moving discontinuously. Although in practice it is unrealistic to assume such distinct zones, it is a helpful concept. The length of the chromatographic bed over which equilibrium is reached is called a 'theoretical plate'.

If the components of a mixture have different partition coefficients in a given chromatographic system, they can be separated if the number of plates is high enough. This process is impeded by the fact that the compound bands become broader as they travel through the layer or column. The effect of band broadening must be less than that of separation, otherwise complete resolution cannot be obtained.

Chromatography is based on the interaction of molecules with molecules (not with a field) and it is inherently governed by time-dominated processes. The  $x$ -axis of a chromatogram is time (and not energy as in spectroscopy). Chromatography and spectroscopy are totally orthogonal techniques, and consequently their online combination (spectroscopic investigation of the separated sample components) is a most powerful approach.

As an example of how efficient chromatography can be, **Figure 2** shows the separation of polymethoxylated flavone isomers found in orange oil by supercritical fluid chromatography with a packed column.

## The Chromatogram

If the compounds are eluted from the chromatographic bed, as is always the case in all types of tubular or column chromatography, usually an instrument, called a detector, is coupled to the outlet that responds to the eluting bands. According to the type of chromatography and to the compounds present in the sample mixture, detectors are highly sophisticated devices but in any case the chromatograms look similar. A simple chromatogram is shown in **Figure 3**.

Owing to the band broadening processes, the bands, now called peaks, are of Gaussian (normal distribution) shape, as in **Figure 3**. In reality, the peaks often show a degree of asymmetry in that the trailing end is broader than the leading one. This phenomenon is known as tailing and for its mathematical description it is possible, for example, to overlay an exponential function.

The nomenclature in **Figure 3** are defined as follows:  $t_0$  is the breakthrough time or dead time (sometimes also called  $t_M$ ); time of a nonretained solute or of the mobile phase itself to travel through the chromatographic bed. The linear velocity of the mobile phase  $u$  (say, in  $\text{mm s}^{-1}$ ) can be calculated from  $t_0$  if the length of the column  $L_c$  is known:

$$u = \frac{L_c}{t_0} \quad [2]$$

$t_R$  is the retention time; time elapsed from sample injection to the maximum of a particular peak.  $t'_R$  is the net retention time,  $t'_R = t_R - t_0$ . For any solute,  $t_0$  represents the time spent in the mobile phase and  $t'_R$  the time spent in the stationary phase. To achieve a separation, the individual compounds of a mixture need to show differing net retention times in a given chromatographic system since on average all molecules spend the same time in the mobile phase.  $w$  is the peak width at the baseline.  $w$  is defined as the intersection of the inflection tangents with the baseline and is four times the standard deviation  $\sigma$  of the Gaussian peak:  $w = 4\sigma$ .

If the chromatographic separation is performed in a plane (paper or thin-layer chromatography), the separated bands are not eluted but remain in the layer. Usually, the development of the chromatogram is stopped before the front of the mobile phase reaches the opposite end of the plane. The separated bands then appear as spots although their concentration profile is also described by a (perhaps distorted) Gaussian function. This becomes obvious if the spots are scanned by a densitometer: a chromatogram as shown in **Figure 3** is obtained. **Figure 4**

**Figure 2** Chromatographic separation of polymethoxylated flavones from orange oil. Method, packed column chromatography with a supercritical mobile phase; column, 4.6 mm i.d.  $\times$  25 cm length; stationary phase, silica 5  $\mu$ m; mobile phase, carbon dioxide–methanol 9:1; column inlet pressure, 220 bar; pressure drop over the column, 20 bar; temperature, 40 °C; detector, UV 313 nm. presents a schematic planar chromatogram with its characteristic definitions.  $z_m$  is the distance from the starting point to the front of the mobile phase and  $z_x$  is the distance from the starting point to the spot center of compound x.

## Concepts Used in Chromatography

The chromatogram allows calculation of the basic parameters of the separation. These are highly useful tools in understanding and optimizing chromatographic

**Figure 3** A schematic elution chromatogram.

**Figure 4** A schematic planar chromatogram.

separations and, most importantly, utilizing the method for chemical analysis, although in some cases their basic scientific justification is weak; this is especially true for the plate number.

### Retention Factor

The scientific description of the appearance of a peak in an elution chromatogram is not given by its retention time but by its retention factor  $k$  (formerly called capacity factor  $k'$ ).

$$k = \frac{t'_R}{t_0} = \frac{t_R - t_0}{t_0} \quad [3]$$

where  $k$  is the mole ratio of a solute compound at equilibrium and is directly related to the partition coefficient  $K$  defined in eqn [1] by the phase ratio (as long as no overloading occurs, i.e. for low-injected sample mass):

$$k_x = \frac{n_{\text{stat}}}{n_{\text{mob}}} = K_x \frac{V_{\text{stat}}}{V_{\text{mob}}} \quad [4]$$

where  $n_{\text{stat}}$  is the number of moles of compound  $x$  in the stationary phase at equilibrium;  $n_{\text{mob}}$  is the number of moles of compound  $x$  in the mobile phase at equilibrium;  $V_{\text{stat}}$  is the volume of the stationary phase in the chromatographic system; and  $V_{\text{mob}}$  is the volume of the mobile phase in the chromatographic system.

If the stationary phase is an adsorbent, its characteristic property is not the volume but its specific surface, usually expressed in  $\text{m}^2 \text{g}^{-1}$  (because the sample molecules do not penetrate into the stationary phase but are retained on its surface only).

In a planar chromatogram the position of a spot is defined by its  $R_F$  value (sometimes called retardation factor) which is given by

$$R_F = \frac{z_x}{z_m} \quad [5]$$

The theoretical relation between  $R_F$  and  $k$  is given by

$$R_F = \frac{1}{1 + k} \quad [6]$$

In practice, deviations from this equation are found owing to nonideal behavior of planar chromatographic separation (e.g., depletion of solvent at the front of the mobile phase).

### Relative Retention, Separation Factor

Two compounds can only be separated if they differ in their respective  $k$  values. This is expressed by  $\alpha$ , the relative retention or separation factor:

$$\alpha = \frac{k_2}{k_1} = \frac{t_{R2} - t_0}{t_{R1} - t_0} = \frac{K_2}{K_1} \quad \text{with } k_2 \geq k_1 \quad [7]$$

A separation is only possible if  $\alpha > 1$ . The higher  $\alpha$  the easier is the separation and the fewer theoretical plates are necessary to resolve two neighboring bands; see eqn [11]. The relative retention is a measure of the inherent ability of a given chromatographic system to separate a mixture of interest, i.e. of its specificity. It has nothing to do with its quality, which is defined by its plate number.

### Theoretical Plate Number and Plate Height

A visual idea of a theoretical plate is presented in **Figure 1**. The mathematical expression of the number of theoretical plates  $N$  in a chromatographic system is obtained from the width of a peak in relation to its retention:

$$N = 16 \left( \frac{t_R}{w} \right)^2 = 5.54 \left( \frac{t_R}{w_{1/2}} \right)^2 = 2\pi \left( \frac{h_p t_R}{A_p} \right)^2 \quad [8]$$

where  $w_{1/2}$  is the peak width at half height of the peak;  $h_p$  is the peak height; and  $A_p$  is the peak area.

The greater the plate number of a chromatographic system, the more difficult the separation problems that can be solved. In principle the number of plates can be increased by using a longer column. Practical problems, mainly the pressure drop across the column and difficulties in manufacturing long packings or capillaries, set a limit at  $\sim 10^5$  plates in all chromatographic techniques.

To describe the quality of a chromatographic system the height equivalent to a theoretical plate, HETP or  $H$ , is more useful than  $N$ :

$$H = \frac{L}{N} \quad [9]$$

where  $L$  is the length of the chromatographic bed.

### Resolution

The separation factor  $\alpha$  describes the chromatographic system and its interaction with a sample from a thermodynamic point of view, but it says nothing about the actual resolution of two peaks. This is done by using the resolution  $R$  which compares the difference between the retention times with the peak widths:

$$R = 2 \frac{t_{R2} - t_{R1}}{w_1 + w_2} = 1.18 \frac{t_{R2} - t_{R1}}{w_{1/2(1)} + w_{1/2(2)}} \quad [10]$$

Two neighboring peaks have  $R = 1$  if their tangents of inflection touch each other at the baseline; their areas have a low degree of overlap. In Figure 2 this is approximately the case for peaks 1 and 2. There is negligible area overlap if  $R > 1.5$  (for peaks of similar size).

Resolution can be described as the interplay of retention factor  $k$ , separation factor  $\alpha$ , and plate number  $N$ :

$$R = \frac{1}{4}(\alpha - 1)\sqrt{N} \frac{k_1}{1 + \bar{k}} = \frac{1}{4} \frac{\alpha - 1}{\alpha} \sqrt{N} \frac{k_2}{1 + \bar{k}} \quad [11]$$

$\bar{k} = (k_1 + k_2)/2$  and it is assumed that  $N_1 = N_2$ . (Other representations of this resolution equation are also used.)

Equation [11] is key to understanding how a chromatographic separation can be influenced. The most important parameter is  $\alpha$  but it is often the most difficult one to change. The influence of  $k$  is rather weak, especially at higher retention factors.  $N$  acts only through its square root, i.e. doubling the length of a column increases the resolution only by a factor of 1.4. For mixtures with a small number of components it is most important to increase  $\alpha$  in order to

be able to perform rapid analyses: a special case is the separation of a pair of enantiomers. If complex mixtures need to be separated it is essential to choose systems with high  $N$  because it is impossible to optimize  $\alpha$  for all components present.

### Peak Capacity

The peak capacity  $n$  is a measure of the performance of a chromatographic system (although analysis time is not directly involved) because it describes how many peaks can be separated with  $R = 1$  within a given 'window' of  $k$  values:

$$n = 1 + \left( \frac{\sqrt{N}}{4} \right) \ln(1 + k_{\max}) \quad [12]$$

where  $k_{\max}$  is the retention factor of the last eluted peak.

Even excellent chromatographic columns have rather low peak capacities (e.g.,  $n = 86$  for  $N = 20\,000$  and  $k_{\max} = 10$ ). The number of adequately resolved peaks in a real chromatogram is in fact markedly lower because their  $k$  values are distributed in an unpredictable manner and because the peaks differ in size (see Statistical Peak Overlap below). A way to overcome this limitation is programmed elution, i.e., running temperature programs or solvent gradients.

### Separation Number, Trennzahl

In gas chromatography a common measure for characterizing the quality of a capillary is the separation number, SN (also called Trennzahl, TZ). This gives the number of peaks that can be placed with resolution  $R = 1.18$  between two members  $n$  and  $n + 1$  of a series of homologs:

$$SN = \frac{t_{R(n+1)} - t_{R(n)}}{w_{1/2(n+1)} + w_{1/2(n)}} - 1 \quad [13]$$

Whereas the plate number can only be determined in non-programmed (isothermal or isocratic) chromatography, SN is always obtained from a gas chromatogram with temperature programming.

### Statistical Peak Overlap

In a chromatographic system the peaks are eluted in accordance with their partition coefficients, i.e. as they are driven or retained by their physicochemical properties with regard to the phase system. For the observer the elution order of complex mixtures resembles an unpredictable pattern and in a first approximation a chromatogram must be looked at as a random mixture of peaks. (Exceptions are homologs, e.g.  $n$ -alkanes in mineral oil samples.)

Partial or total peak overlap is a common phenomenon that has to be taken into account.

If  $m$  detectable analytes are present in the sample and if the chromatographic system has a peak capacity of  $n$ , then the average number  $p_x$  of  $x$ -tets (fused peaks that are composed of  $x$  single-component peaks) is

$$p_x = m \cdot e^{-2m/n} (1 - e^{-m/n})^{n-1} \quad [14]$$

In other words, the probability  $P$  that a given peak is single-standing with resolution  $R \geq 1.0$  is

$$P = e^{-2m/n} \quad [15]$$

In a chromatogram of 10 compounds, to be separated on a system with peak capacity 45, one can expect to find 6 or 7 singlets ( $p_1 = 6.4$ ), at least one doublet ( $p_2 = 1.3$ ), and perhaps even a triplet ( $p_3 = 0.25$ ). The probability that a peak of interest will be resolved is  $P = 0.64$  or almost two-thirds. This situation is shown in Figure 5.

**Figure 5** Artificial chromatograms generated with random numbers. Programmed separations are simulated with  $t_0 = 100$  s, end of chromatogram at 1000 s, and a peak capacity of 45. The width of each peak is 20 s. Peak sizes can vary between 1 and 100 area units. Ten compounds are present but none of the three chromatograms shows them all.

## Reduced Parameters

From an engineer's point of view it is highly desirable to describe the chromatographic system by reduced parameters. This helps to understand some very basic principles of chromatography and to compare very different systems. Reduced parameters are dimensionless. Instead of the plate height  $H$  and mobile phase linear velocity  $u$ , one defines the reduced plate height  $h$  and the reduced velocity  $v$  by the following two equations:

$$h = \frac{H}{d} \quad [16]$$

where  $d$  is the characteristic length of the chromatographic system; for packed columns this is the particle diameter, for open capillaries this is the diameter of the capillary:

$$v = \frac{ud}{D} \quad [17]$$

where  $D$  is the diffusion coefficient of the solute in the mobile phase.

If the quality of chromatographic columns is to be compared,  $h$  is a good measure because it is independent of their physical dimensions. In chemical engineering  $v$  is known as the Peclet number; it relates the carrier flow velocity to the diffusion coefficient, which is the parameter that limits the speed of chromatography. To obtain optimum results from a given chromatographic system,  $v$  should be kept within a well-defined range.

For all chromatographic techniques the time needed for an analysis can be predicted from plate number  $N$ , reduced plate height  $h$ , characteristic length  $d$ , reduced velocity  $v$ , diffusion coefficient  $D$ , and retention factor of the last eluted peak  $k_{\text{last}}$ :

$$t_R = \frac{Nhd^2}{vD} (1 + k_{\text{last}}) \quad [18]$$

## Band Broadening and the van Deemter Curve

As mentioned in the discussion of Figure 1, the bands become broader during their passage through the chromatographic bed. Several very different reasons are responsible for this unwanted behavior.

1. Eddy-diffusion and flow distribution, which occur in packed beds. Not all sample molecules travel along the same paths and these paths are not straight, therefore their residence times in the mobile phase differ. Moreover, the flow velocity between the particles of the stationary phase is not uniform but

exhibits a parabolic distribution, which again allows some molecules to travel faster than others. This is the so-called *A*-term of the van Deemter equation (see below). It is nonexistent for open capillaries. In packed columns it can be kept low by using particles of as uniform a size as possible.

2. Longitudinal diffusion. The sample molecules are not only transported passively by the mobile phase, they also move back and forth through their own diffusion. This effect cannot be influenced because it depends on the diffusion coefficient, but it is not (or should not be) a problem since it only manifests itself if the chromatographic process is too slow. However, then, it affects the separation significantly. This is the *B*-term.

3. Resistance to mass transfer between the mobile and stationary phase. It takes the solute molecules some time to reach the stationary phase, to enter it, to remain there for a duration that is governed by statistics, and to leave the stationary phase and enter the mobile phase again. Molecules that in the same period are not engaged in mass transfer will be well ahead, along the chromatographic bed, thereby broadening the band. This is the *C*-term. It can be kept low by using low-viscosity mobile phases, packed columns with very fine particles, open capillaries of small inner diameter, and thin films of the stationary phase if this is a liquid.

Although a detailed theory of band broadening is complicated, it can be presented in a simple form through the van Deemter equation, which expresses the plate height *H* or the reduced plate height *h* as a function of *A*, *B*, *C*, and the linear flow velocity of the mobile phase:

$$H = A + \frac{B}{u} + Cu \quad [19a]$$

$$h = Av^{1/3} + \frac{B}{v} + Cv \quad [19b]$$

The equation  $H = f(u)$ , the van Deemter equation, is shown in Figure 6. One sees that *H* has a minimum at an optimum flow velocity that can be determined empirically or by knowledge of *A*, *B*, and *C* (which in many cases is not difficult). It is not recommended to work in the region left of the minimum because here the *B*-term becomes strongly dominant. If the *A*-term is missing, as in open capillaries, the minimum plate height will be decreased. Most important is the *C*-term because it limits the speed of chromatography: it is possible to work in the region to the right of the minimum, but only with a certain sacrifice of separation quality.

**Figure 6** The van Deemter curve, which describes the dependence of the height of a theoretical plate *H* on the linear flow velocity of the mobile phase *u*. Values are typically *H* in  $\mu\text{m}$ , *u* in  $\text{mm s}^{-1}$ .

## Chromatographic Analysis

Chromatography can be used for both qualitative and quantitative analysis.

### Qualitative Analysis

The retention time (as an easily determined value, especially when an electronic registration device is used), or more rigorously, the retention factor, and in planar chromatography the  $R_F$  value, are physico-chemical characteristics of a pure compound in a given chromatographic system. However, this system needs to be thoroughly defined. This means that the type of the stationary phase (and even the brand and batch), the composition of the mobile phase and its flow rate, the temperature and pressure, the column dimensions, and the detector properties all need to be known and kept more or less constant for a given analysis. Even the composition of the sample (e.g. the solvent used for dilution) can have a distinct influence on the separation. Owing to the limited peak capacity of all chromatographic methods, a *k* value determined in one system is not real proof of identity. It is also necessary to perform the analysis on a very different system (a good example would be adsorption and partition chromatography) and to compare again with a pure standard. Alternatively, positive identification can be obtained by coupling to a spectroscopic technique that provides additional qualitative information, especially mass spectrometry.

### Quantitative Analysis

It is a convenient fact that both the peak area and peak height of a well-defined (not necessarily Gaussian) peak are proportional to the mass of compound registered by the detector. This means that quantitative analysis can easily be performed using common techniques such as external or internal

standardization or standard addition. However, good resolution from all neighboring peaks is a prerequisite; poor resolution is prone to producing erroneous results and should be avoided whenever possible. The signal-to-noise ratio of the peak should be higher than 10. Even when these basic principles are observed, numerous pitfalls await the analyst. They can only be avoided by experience, by knowledge of the relevant literature, and by always being alert and aware of what one is doing. As a result chromatography can be considered a most powerful, rapid, and versatile technique.

### Limitations of One-Dimensional Chromatography

Chromatography currently serves as the premier technique for the separation and analysis of an extensive range of samples and sample types, since intrinsic properties of the sample analytes can be accommodated by selecting the appropriate type of chromatography. For example, volatile compounds will be usually analyzed by gas chromatography (GC). One-dimensional chromatography can be defined as the use of one particular chromatographic method that utilizes only one basic mechanism (and one type of stationary and mobile phase) for component separation. The resolving power of a particular or discrete chromatographic separation can be evaluated in terms of its ‘peak capacity’, a term that was introduced in 1967 by Giddings to represent the number of compounds that can be placed side by side in a separation channel with a given minimum resolution performance for neighboring components. This concept assumes that compounds are evenly positioned in the separation dimension.

Unfortunately, the composition of complex samples when subjected to chromatographic analysis will ensure a more ‘random’ displacement of components in the separation space, with multiple occurrences of peak overlap. This is the main hindrance to one-dimensional chromatography for adequate sample analysis. In order to reduce the amount of peak overlap, one must significantly inflate the peak capacity of the chromatographic system, such that the peak capacity is excessively high compared to the actual number of components in the sample. This may not always be possible (depending upon the chromatographic system used), or can be achieved only at the expense of dramatically increasing the analysis time to obtain reasonable analyte resolution. Alternatively, multidimensional chromatography, which offers superior peak capacity compared to one-dimensional methods, can be used for the successful analysis and separation of complex samples.

### Multidimensionality in Chromatography

Multidimensional chromatography can be defined as the coupling of two or more chromatographic displacement systems for enhanced sample resolution. **Figure 1** is representative of the key features of a two-dimensional separation system. In respect of

standardization or standard addition. However, good resolution from all neighboring peaks is a prerequisite; poor resolution is prone to producing erroneous results and should be avoided whenever possible. The signal-to-noise ratio of the peak should be higher than 10. Even when these basic principles are observed, numerous pitfalls await the analyst. They can only be avoided by experience, by knowledge of the relevant literature, and by always being alert and aware of what one is doing. As a result chromatography can be considered a most powerful, rapid, and versatile technique.

### Limitations of One-Dimensional Chromatography

Chromatography currently serves as the premier technique for the separation and analysis of an extensive range of samples and sample types, since intrinsic properties of the sample analytes can be accommodated by selecting the appropriate type of chromatography. For example, volatile compounds will be usually analyzed by gas chromatography (GC). One-dimensional chromatography can be defined as the use of one particular chromatographic method that utilizes only one basic mechanism (and one type of stationary and mobile phase) for component separation. The resolving power of a particular or discrete chromatographic separation can be evaluated in terms of its 'peak capacity', a term that was introduced in 1967 by Giddings to represent the number of compounds that can be placed side by side in a separation channel with a given minimum resolution performance for neighboring components. This concept assumes that compounds are evenly positioned in the separation dimension.

Unfortunately, the composition of complex samples when subjected to chromatographic analysis will ensure a more 'random' displacement of components in the separation space, with multiple occurrences of peak overlap. This is the main hindrance to one-dimensional chromatography for adequate sample analysis. In order to reduce the amount of peak overlap, one must significantly inflate the peak capacity of the chromatographic system, such that the peak capacity is excessively high compared to the actual number of components in the sample. This may not always be possible (depending upon the chromatographic system used), or can be achieved only at the expense of dramatically increasing the analysis time to obtain reasonable analyte resolution. Alternatively, multidimensional chromatography, which offers superior peak capacity compared to one-dimensional methods, can be used for the successful analysis and separation of complex samples.

### Multidimensionality in Chromatography

Multidimensional chromatography can be defined as the coupling of two or more chromatographic displacement systems for enhanced sample resolution. **Figure 1** is representative of the key features of a two-dimensional separation system. In respect of

**Figure 1** Schematic diagram of a multidimensional chromatography system. The two systems correspond to the methods employed, e.g., the GC or LC system. The separation channel may be an elution column or separation plane. Between the two systems is the process for transferring solute from the first to second dimensions. It may be a heart-cut process (GC–GC), a fraction collection step (LC–GC), a modulation process (GC  $\times$  GC), or a plate positional change for planar TLC. Some systems will allow or require a detection step between the two systems, such as a monitor detector in MDGC. In the figure, step 1 refers to the sample application/injection; step 2 to the interface or intermediate sample-processing device; and step 3 to the elution of the separated sample into a detection system.

separations, about two dimensions is the practical limit of such a system, although a higher-dimension analysis system can be devised if a third dimension comprising a spectroscopic detection step (e.g., mass spectrometry) is added. Multidimensional separation methods are particularly amenable to the analysis of complex samples since different separative mechanisms are exploited in each of the separate dimensions for the ultimate resolution of sample components. Successful separations are easily achieved, due to the expanded peak capacity of the multidimensional system. The extent of peak capacity enhancement will depend upon the type of multidimensional system used, and how eluate fractions from the first dimension are transferred to the subsequent dimension(s). This is an important aspect, which needs further elaboration.

Multidimensional techniques may be classified as hyphenated or comprehensive, depending upon the method of effluent transfer between coupled dimensions. The historical origins of multidimensional chromatography derive from simple heart-cutting techniques whereby only a specific retention region(s) is isolated and directed to the second dimension for further separation. This type of multidimensional separation represents a ‘hyphenated’ method, and is denoted using the hyphen symbol, for example, liquid chromatography–gas chromatography (LC–GC). In this example, selected effluent fractions from the LC are isolated and further separated by GC. The peak capacity of such hyphenated systems is the sum of the individual peak

capacities of the systems that are coupled. In comparison, comprehensive methods ensure that all solutes in the sample are fully subjected to each separation dimension of the multidimensional system in an independent or orthogonal manner. This can be achieved by directing all of the effluent from the first dimension to the subsequent dimension, or otherwise, taking a representative fraction of the effluent and directing it to the coupled dimension. What is fundamental in the latter instance is that the second dimension faithfully samples all peaks eluting from the first dimension. In comprehensive systems, the resulting peak capacity is the product of the individual peak capacities, and the multiplex sign is used to indicate a comprehensive multidimensional chromatography system (e.g., LC  $\times$  GC). It is important to recognize that simply joining two columns together and allowing solutes to pass directly through the two-column set without hindrance does not satisfy the definition of a comprehensive two-dimensional separation. It is clear that the most substantial gains in peak capacity are achieved using comprehensive multidimensional chromatography systems as opposed to hyphenated systems. This can be expressed mathematically using the following equations where total peak capacity ( $n_{\text{tot}}$ ) is expressed as

$$n_{\text{tot}} = \sum_{i=1}^m n_m$$

for a hyphenated system with  $m$  dimensions, each of capacity  $n_m$ ; and

$$n_{\text{tot}} = \prod_{i=1}^n n_m$$

for a comprehensive system with  $m$  dimensions.

**Figure 2** further illustrates the concept of hyphenated and comprehensive multidimensional chromatography with respect to total peak capacity. In the figure, the single channel separation in ‘A’ is represented as an equivalent capacity diagram in ‘B’. The conventional multidimensional method traditionally selects a given region to apply to the second dimension, which then yields greater capacity for that selected region, as shown in ‘C’. The total capacity is expanded by the additional capacity of each selected region. However, only a few regions can usually be subjected to the second dimension. In the comprehensive method, by employing a suitable interface and a higher sampling frequency from first to second dimension, it is possible to apply the multidimensional method to the whole first dimension displacement. ‘D’ illustrates this concept.

Giddings defined two main parameters, which are fundamental to multidimensional separations. The

**Figure 2** A schematic illustration comparing the peak capacities of chromatographic systems with different dimensionalities. (A) shows the one-dimensional chromatographic trace, and (B) represents the equivalent one-dimensional peak capacity. (C) and (D) show the comparative gains in peak capacity achieved using a hyphenated two-dimensional system and a comprehensive two-dimensional system, respectively.

first simply states that components of a mixture must be subjected to two or more separation steps or mechanisms in which their displacements depend on different factors. The second, however, is critical, and states that when two or more components are substantially separated in a single step, the integrity of the separation must be maintained until the completion of the separative operation. Adherence to the latter parameter may therefore rule out single tandem (directly coupled) column arrangements whereby components separated by the first column may remerge on the second column.

The beauty of multidimensional chromatography rests in the fact that adequate separation of two components along any separation axis is sufficient for their ultimate resolution. This means that there can still be serious component overlap along any one axis, so long as physical deconvolution occurs along another axis. Superior multidimensional systems, however, depend upon the coupling of powerful one-dimensional systems whereby the final resolution achieved is dependent upon differences between the two (or more) dimensions. The highest resolution is gained when there is no correlation between the

separation mechanisms, in which case we say that the mechanisms are 'orthogonal'. This means that the mechanisms used for separation are very much different. A simple example of an orthogonal multidimensional system would be LC–GC (or LC  $\times$  GC) since in the LC case, the mobile phase is a liquid, and separation arises due to (for example) compound hydrophobicity, whereas in the GC system, the mobile phase is a gas, and separation is determined by compound boiling point or volatility. There is no correlation between the two separation methods; they are orthogonal, and hence the resulting dimensionality of the system is 2.

Dimensionality is an important term, which can be used to describe the nature of the sample, or of the multidimensional system. System dimensionality simply refers to the number of coupled separation stages or dimensions used in the multidimensional system. For example, a single column liquid chromatograph would have a dimensionality of 1, whilst a LC–GC system described above has a dimensionality of 2. On the other hand, sample dimensionality, introduced by Giddings in 1995, is used to describe the intrinsic nature of the sample, and can be defined

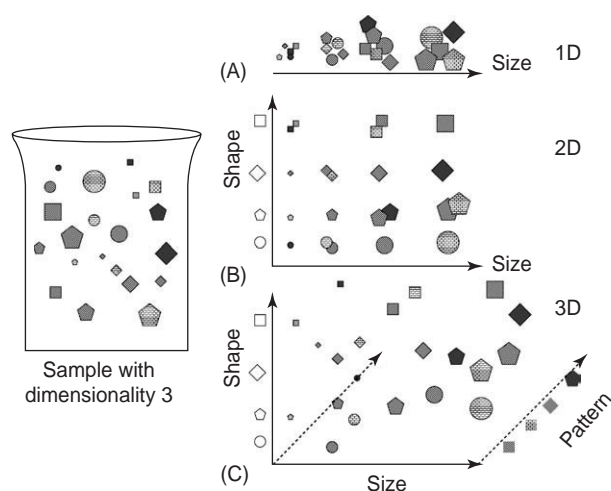

as the number of individual variables that must be specified to identify components in a sample. For example, in a mix containing only straight chain alkanes, the sample dimensionality would be based exclusively upon carbon number, thus yielding a dimensionality of 1. Naturally, as the sample becomes more complex, composed of multiple chemical classes (e.g., aromatics), more parameters or mechanisms of separation would be needed to define the sample, therefore, increasing its dimensionality. It is also important to consider whether we have available separation tools that can be employed to resolve or differentiate the identified sample dimensionality. If not, then these sample dimensions would collapse into a single dimension.

Theoretically, optimum separation is achieved when the sample dimensionality and system dimensionality are equivalent, resulting in an ordered separation (Figure 3). In the above example, only one separation dimension would be required to analyze the alkane sample. If, however, the dimensionality of the sample exceeds that of the system, sample components will not be resolved in an orderly fashion, but rather a disordered or chaotic separation will result. In Figure 3, three descriptors are required to define the sample – shape, pattern, and size. In a chemical sense, these might be molar mass, polarity, and molecular shape. As more dimensions of separation are applied, greater definition of the mixture components is achieved. Unfortunately, for very complex samples, the sample dimensionality will be

significantly greater than the system dimensionality, since the development of a multidimensional system with a system dimensionality equivalent to that of the sample cannot be achieved. Alternatively, a multidimensional system with a system dimensionality greater than the sample dimensionality is merely wasted, in that the increased peak capacity of the system will not yield any significant improvement in separation of the sample. For example, if a sample is comprised of straight chain and branched alkanes (sample dimensionality 1), then a system of dimensionality greater than 1 will probably not provide any further separation advantage than a single separation dimension. In contrast, a sample comprising alkanes and aromatics (sample dimensionality 2) will require a system dimensionality of 2 to provide full class separation. In this case, a nonpolar GC column in the first dimension, and a second column with a stationary phase of high percentage phenyl content (which retains aromatic compounds compared to aliphatics) should provide separation of alkanes and aromatics that had coeluted on column 1. Clearly, knowledge of sample dimensionality should therefore be exploited, when possible, to enable the most appropriate multidimensional technique to be chosen to suit the sample type.

## History of Multidimensional Chromatography

The origins of multidimensional chromatography derive from paper chromatography, with the realization that different eluents could be applied to the paper stationary phase in different directions. This procedure soon progressed with the development of two-dimensional thin-layer chromatography (TLC) by Kirchner and his team in 1951. Development of multidimensional column chromatography techniques came later, and in 1958, the first multidimensional GC analysis (GC–GC) was conducted by Simmons and Snyder for the analysis of C<sub>5</sub>–C<sub>9</sub> petroleum fractions. This system, referred to as ‘two-stage gas–liquid chromatography’, utilized a valve for the online transfer of heart-cut fractions from the first (nonpolar) column to the second (polar) column. The development of multidimensional LC, however, proceeded at a much slower pace, and it was not until 1978, 20 years after the development of multidimensional GC, that an online multidimensional LC system (LC–LC), utilizing orthogonal columns was developed by Erni and Frei for the analysis of complex plant extracts. The first dimension was composed of a gel permeation chromatographic column, whilst a reversed-phase column was used as the

**Figure 3** Schematic illustration showing the successive improved resolution of a three-dimensional sample mixture comprising dimensions ‘shape’, ‘size’, and ‘pattern’. (A) The 1D separates by size, but this leads to poor resolution of pattern and shape; (B) adding a shape selective dimension leaves some overlapping pattern components; and (C) only the three-dimensional system permits full resolution of all components.

second dimension. Heart-cut fractions from the first column were collected and transferred to the second column using an eight-port dual loop injection valve.

It is beyond the scope of this article to trace the development of all hyphenated multidimensional chromatographic systems, since this would also encompass the development of hyphenated chromatographic and spectroscopy techniques (such as LC-MS) and also chromatography coupled to electrophoretic techniques such as liquid chromatography-capillary electrophoresis (LC-CE). What is important to realize is that multidimensional chromatography was initially conducted using hyphenated systems, since hyphenated couplings could be achieved simply, and enabled the better characterization of specific regions of retention complexity via heart-cutting. Peak capacity gains were significant, but only amounted to the addition of the individual component peak capacities for each time a given dimension is employed. Subsequently, these methods then progressed to comprehensive techniques capable of producing multiplicative gains in peak capacity.

The first report of comprehensive two-dimensional chromatography was made by Bushey and Jorgenson in 1990 using LC  $\times$  LC. A microbore cation exchange column was used as the first dimension, and operated under gradient elution conditions. Effluent from this column was collected using an eight-port valve, and forced onto a second, size exclusion, column using a second LC pump. The entire system was automated and operated under computer control, and in this system, the entire first column effluent was separated by the second column, yielding a comprehensive analysis. It is noteworthy that LC  $\times$  CE was also developed by Bushey and Jorgenson, but in this instance, only 5% of the LC effluent was applied to and separated by the CE step. Still, this analysis can be considered as comprehensive since all LC peaks were representatively sampled and separated on both dimensions. In the following year, comprehensive GC  $\times$  GC was introduced by Liu and Phillips. In this work, a two-stage elevated temperature (thermal) modulator was used to interface two serially coupled and somewhat orthogonal GC columns. The modulator used ensured the comprehensive analysis of the entire solute composition of a hydrocarbon standard mixture and a coal liquids sample. The development of the principles of comprehensive separation systems in these landmark studies has served as the foundation for the development of many more comprehensive chromatography technologies, which are currently in use today.

The most obvious benefit of comprehensive analyses rests in the multiplicative gains in peak capacities that are attainable when orthogonal dimensions

are coupled in such a way as to yield the comprehensive result. Furthermore, the need for timed heart-cuts, as mandated in multidimensional analyses for selection of target regions, are redundant in comprehensive systems, thereby simplifying the potential for automation. Critical to the success of comprehensive multidimensional systems is that the interface between the coupled systems should be reliable and ensures the faithful transferring of solutes from one dimension to the next. At present, the focus of much research is the development of improved interfaces, for example, in GC  $\times$  GC, the development of improved modulators.

## Two-Dimensional Planar Chromatography and Coupled-Column Chromatography

There are two distinct approaches used when undertaking multidimensional chromatography. The first is known as two-dimensional planar separation, or discrete separation, which is achieved by using the two right angle dimensions of a continuous surface or thin film bed for separation. This technique derives from paper chromatography, and has progressed to such methods as multidimensional thin-layer chromatography (MD-TLC). Discrete separation is achieved since an isolated sample is applied to the two-dimensional bed, generally at a corner position, and development proceeds along the two planar axes. Spots, corresponding to individual compounds, appearing at discrete positions on the planar surface reflect the resulting separation.

The second type of multidimensional chromatography is coupled column or continuous separation. As the name suggests, this technique relies on serially coupled chromatography columns for sample resolution. Partially resolved effluent fractions from the first column are sequentially directed to a second column, or series of columns, with different separation capabilities, for subsequent separation. It is important in this multidimensional method that the columns are carefully chosen to maximize their orthogonality to ensure optimum resolution is achieved. Furthermore, for the success of this method, it is important that the effluent cuts taken from the first column are sufficiently small so as to minimize the number of components in each cut, and therefore increase the probability of their ultimate separation. Typically, cuts are taken at about the duration of peak standard deviation timescale. This ensures the first dimension separation is not significantly degraded.

Choosing between a two-dimensional planar separation and a coupled column separation will largely depend upon the sample type and its complexity. Contrasting the two techniques shows that planar separations give a very broad characterization of the sample. These techniques are generally quite simple to incorporate, and the two-dimensional separation is clearly illustrated and easily interpreted. Quantification of the isolated components, however, is complex. The main advantage of two-dimensional planar chromatography, however, is that if sufficiently good resolution is achieved along one axis, the separation cannot be destroyed by any relative displacement along the second axis. This is not always the case in coupled column separations whereby separation in the first dimension is not always maintained in the subsequent dimension(s), and components can remerge, thus ruining the initial resolution. Nevertheless, coupled column chromatography systems are advantageous because they can be used to target particular areas of complexity in the elution space through the collection of specific eluate fractions. These fractions can then be further separated as necessary. Furthermore, additional separation mechanisms can be easily added to the existing coupled column arrangement, giving the coupled column arrangement significant flexibility. The use of conventional detectors simplifies quantification.

## Considerations for Multidimensional Couplings

In order to maximize the resolving power of multidimensional systems, very different, and uncorrelated, one-dimensional systems should be coupled. When high correlation occurs, the two-dimensional (or  $n$ -dimensional) space effectively reduces back to a

one-dimensional (or lower-dimensional) space with little improvement in separation power. Ideally, one-dimensional systems with high peak capacities should be coupled, since according to the statistical model of overlap theory, a sample should have fewer components than 37% of the column peak capacity in order to be relatively certain that acceptable peak resolution in a one-dimensional system can be achieved for a purely random analysis.

However, for various reasons coupling of particular one-dimensional systems will not always produce effective multidimensional separations, and therefore couplings should be carefully considered. First, consideration should be given to the sample type and properties, and whether it is amenable to analysis by a certain chromatographic method. It would be illogical, for example, to analyze uncharged species using ion chromatography (IC). Secondly, coupling of chromatographic methods must be physically compatible with respect to mobile phase composition (Table 1); whilst multidimensional GC is relatively straightforward, direct coupling of particular LC methods, such as normal-phase (NP) with reversed-phase (RP) chromatography, are generally problematic due to the incompatibility of the two mobile phases. Mobile phase incompatibility can sometimes be accommodated, but this will depend on the separative displacement processes used by the coupled chromatographic system. Likewise, a GC step can follow a suitable liquid-phase separation such as NP-LC, but LC will not be appropriate as a downstream separation procedure after a GC first dimension – the gas phase separated solutes cannot be effectively re-introduced into a liquid phase.

Giddings introduced the notion of a sequential or simultaneous displacement process to characterize the type of displacement used in a multidimensional arrangement. Thus, a sequential displacement is

**Table 1** Compatibility table: Possible couplings of selected two-dimensional column chromatographic systems based upon dimension compatibility. Note that the coupling order is important. Entries do not imply that the method has been implemented in practice. The coupling may be online direct coupling (e.g., GC–GC) or may involve special interfaces that allow phase isolation in the coupled method (e.g., vaporization of liquid phase in discrete sampling injection in NP-LC–GC)

First dimension	Second dimension						
	GC	NP-LC	RP-LC	SFC	IC	CE	SEC
GC	✓						
NP-LC	✓	✓				✓	✓
RP-LC	✓		✓			✓	✓
SFC	✓	✓		✓			✓
IC					✓	✓	
CE	✓					✓	✓
SEC	✓	✓	✓		✓	✓	✓

GC, gas chromatography; NP-LC, normal-phase liquid chromatography; RP-LC, reversed-phase liquid chromatography; SFC, supercritical fluid chromatography; IC, ion chromatography; CE, capillary electrophoresis; SEC, size exclusion chromatography.

essentially achieved using two (or more) separation processes, which occur in different media, under different conditions. The initial separation achieved in the first dimension is transferred in linear zones to the subsequent dimension of differing composition, for further displacement. Sequential multidimensional separations therefore offer significant flexibility to the analyst, and can be used to overcome mobile phase incompatibilities between the systems. Thus, using the example described in the previous paragraph, fractions eluting from a normal-phase separation could be collected, evaporated to dryness, and reconstituted in a polar solvent, which would be compatible for subsequent separation using a reversed-phase system.

Conversely, simultaneous displacements are much more rigid, in that the displacements take place in the same media, under the same conditions, such as in the same or similar solvent, at the same temperature and pressure. Therefore, chromatographic techniques using different states of mobile phases (i.e., gas, liquid, or solid) cannot be described as simultaneous. In 1984, Giddings described the coupling of chromatographic methods for simultaneous displacements as redundant, and predicted that no combination would enhance the separation gained under one-dimensional analysis; enhanced separation would only occur by coupling a chromatographic method with a separative method based upon field-induced displacements, such as electrophoresis. However, it cannot be disputed that GC  $\times$  GC using coupled, 'somewhat orthogonal' columns inside a single GC oven constitutes a powerful multidimensional system achieved using simultaneous displacement.

Sequential multidimensional chromatographic methods can be conducted either online or offline. A typical offline LC–GC method will be the collection of polarity-defined fractions of an oil separated by NP-LC into saturates, cyclics, aromatic, heteroatomic fractions, etc., with subsequent separation of each fraction by high-resolution GC. Similarly, NP-LC can be successfully coupled online with GC. In the online set up, fractions from the liquid chromatograph are transferred to the gas chromatograph using one of two techniques. The first is known as 'concurrent eluent evaporation'. In this method, as the name suggests, the eluate from the liquid chromatograph is completely evaporated during its introduction into the gas chromatograph injector. This method is simple and enables relatively large volumes of LC effluent to be transferred; however, it is restricted to the analysis of solutes with intermediate-to-high elution temperatures. The alternative is known as the retention gap method, whereby a valve

is positioned between the LC and GC interface, and an on-column injector and uncoated precolumn and retaining column are positioned prior to the analytical GC column. Sample is introduced into the GC at a temperature below that of the LC eluent boiling point, resulting in solvent trapping effects. The retention gap method is best used for the analysis of highly volatile solutes since the solutes of interest must elute at least 50°C above the boiling point of the mobile phase. In fact, the retention gap method is undermined by the introduction of nonvolatile materials, which may build up in the precolumn causing peak broadening, and is not compatible with water-containing LC eluents since water reacts with the precolumn and can cause active sites within the retention gap.

Online techniques have the advantage of being more rapid than offline techniques. Online processes can be automated and ensure higher sample throughputs as opposed to offline processes. Generally, the mobile phases of the coupled methods need to be compatible, or else the equipment must be capable of performing a suitable solvent changeover prior to the solutes entering the next column. Often, online multidimensional systems will require additional equipment such as valves and pumps, which will require increased technical maintenance, and vigilance to ensure devices such as valves perform consistently for chromatographic reproducibility. On the other hand, offline techniques are generally quite simple to incorporate and do not require any additional sophisticated equipment. However, these techniques have the disadvantage of requiring more time, in that solvent evaporation may be required, or modification of the first dimension fractions must be undertaken prior to subsequent chromatography. The need for increased sample handling of the fractions can be detrimental to solute recovery, and can introduce the risk of sample contamination.

## Status of Multidimensional Chromatography

It is only in recent decades that multidimensional chromatography has been given adequate attention, and the capabilities of multidimensional chromatographic systems realized. Still, the general practice of multidimensional chromatography, as opposed to conventional one-dimension analysis, is limited, as is the awareness and/or appreciation of these techniques. Fortunately, once a chromatographer learns about multidimensional techniques that can be applied to their own field of work, their fascination and curiosity surrounding such techniques is

usually aroused. Work which may have taken extensive periods of time and required tedious sample preparation using one-dimensional chromatography can be replaced with new and faster methods offering unsurpassed and almost unimaginable possibilities for solute resolution. Sample preparation prior to instrumental analysis can be reduced, and multidimensional methods can be used for sample enrichment and selective resolution. Thus, there are ample opportunities available to chromatographers, and attendant advantages from, application of multidimensional separations for sample analysis.

There is often a misconception that multidimensional systems are difficult and costly to set up and implement as a routine tool for analysis. It is true that in some instances additional equipment such as pumps and switching valves for multidimensional LC methods will need to be purchased, but once correctly installed, the costs and additional system maintenance required is insignificant when the improvements in resolution are considered, especially when most online multidimensional techniques proceed in the same time it would take to achieve a typical one-dimensional separation. Currently, some comprehensive techniques, such as GC  $\times$  GC, are overshadowed by a lack of computer software for integration purposes and data reduction. However, it is only a matter of time before user-friendly multidimensional data presentation packages are developed and are commercially available.

At present, most multidimensional chromatography methods are two-dimensional, composed of two one-dimensional systems coupled together. It is foreseeable that these two-dimensional technologies will proceed to three-dimensional systems and beyond. As the number of dimensions increases, and peak capacity further expands, more specific and unambiguous information is gained from each dimension, resulting in superior sample characterization possibilities. It can be predicted that in the future one-dimensional chromatographic analyses of complex samples will be redundant, replaced with faster and more efficient multidimensional methods.

In this article, the role of the detector has not been discussed. At the minimum the detector operates and is chosen exactly as that in a one-dimensional chromatography experiment. Whilst it was alluded

that spectroscopic detection constitutes a second dimension in a two-dimensional (hyphenated) analytical system, it is apparent that multidimensional separations with spectroscopic detection may be termed a three-dimensional system. The obvious and most powerful implementation of this is the use of mass spectrometry. Discussion of chromatography–mass spectrometry is beyond the scope of this article, and the reader is referred to appropriate articles in this text.

## Introduction

The special interest that exists for chromium arises from the fact that chromium in its trivalent oxidation state is considered to be essential for human and animal nutrition, while the hexavalent species have been identified as being toxic, causing cancer and DNA damage. On the other hand, chromium in its various forms is of commercial importance in a wide range of products meeting not only the perceived needs of the society but also leading to a significant emission of chromium to the environment. Since both the chemistry and the biological activity of chromium compounds depend on the valence state of chromium, it is evident that the determination of total concentrations for answering questions about risks for man and its environment is not only insufficient but irrelevant. Speciation analysis can seldom be more significant for the understanding of the behavior of a metal in the natural or occupational environment than it is in the case of chromium. The determination of the distribution of chromium between the two mainly occurring oxidation states, however, is a challenging analytical task, since the analytical approach has to assure that possible transformations between the two forms during sampling, sample preparation, separation, and detection do not occur or at least do not corrupt the analytical result.

## Origin and Nature

Chromium is the seventh most abundant element on earth, most chromium residing in the core and mantle. In the earth's crust chromium ranks 21st, the average concentration being estimated to be  $185 \text{ mg kg}^{-1}$ , much lower than that for the earth as a whole, estimated to be  $3700 \text{ mg kg}^{-1}$ . In its crustal distribution, it shows a particular preference for ultrabasic and basic rocks and specifically eschews the feldspar minerals. Apart from the rare mineral crocoite ( $\text{PbCrO}_4$ ) all naturally occurring chromium is found in the trivalent state. The most important and only commercial source of chromium is chromite ore, in which the chromic oxide content falls typically within the range 15–65%. The main deposits

are in southern Africa with 96% of the known reserves.

## Chemical and Physical Properties

Chromium, a member of Group VIB of the periodic table, exists in four stable isotopes with the following abundance:  $^{50}\text{Cr}$  (4.31%),  $^{52}\text{Cr}$  (83.76%),  $^{53}\text{Cr}$  (9.55%), and  $^{54}\text{Cr}$  (2.38%). It has five short-living radioactive isotopes (half-life in brackets),  $^{48}\text{Cr}$  (23 h),  $^{49}\text{Cr}$  (41.9 min),  $^{51}\text{Cr}$  (27.8 days),  $^{55}\text{Cr}$  (3.5 min), and  $^{56}\text{Cr}$  (5.9 min), but only  $^{51}\text{Cr}$  is commonly used for tracer studies. Some of the basic physical properties of chromium are summarized in Table 1.

Chromium is a steel-gray, lustrous, hard, brittle metal that takes a high polish. It dissolves readily in nonoxidizing mineral acids but not in cold aqua regia or nitric acid because of passivation. Because of this resistivity against oxidizing attack, chromium is widely used as a protective corrosion inhibitor. The inorganic chemistry of chromium is not only rich in its variety of colors (which was the basis for the naming of the element), but also in its many oxidation states and the geometry of its compounds. Being a typical transition metal, chromium can occur in any of the oxidation states from  $-II$  to  $+VI$ , but it is not commonly found in oxidation states other than 0, III, and VI. Chromium can be present in the environment as  $\text{Cr(VI)}$  or  $\text{Cr(III)}$ , the latter can be present either in soluble form or in particulate form.

## Types of Compounds

$\text{Cr(III)}$  exhibits a  $d^3$ -electron configuration and forms many compounds including numerous complexes with oxygen and nitrogen being the preferred coordination partners (Table 2). Kinetically, these compounds are inert in keeping with the half-filled  $t_{2g}$  level of the  $d^3$ -configuration in octahedral geometry. The violet hexaquo species is inert to ligand exchange, with a ligand exchange rate of  $k = 3.5 \times 10^{-6} \text{ s}^{-1}$ , i.e., a half-life of a few days.

Cr(III) hydroxo complexes are expected to be the dominant species in natural waters, including  $\text{CrOH}^{2+}$ ,  $\text{Cr(OH)}_2^+$ ,  $\text{Cr(OH)}_3^0$ ,  $\text{Cr(OH)}_4^-$ ,  $\text{Cr}_2(\text{OH})_2^{4+}$ , and  $\text{Cr}_3(\text{OH})_4^{5+}$ . Polynuclear complexes

of Cr(III) have been reported in the literature, but these species are of no significance in natural systems, especially in solutions of low total chromium concentrations. Under the assumption of thermodynamic equilibrium, the distribution of these complexes can be calculated from thermodynamic data shown in reactions [I]–[V]:

Cr(VI) exhibits  $d^0$ -electron configuration and forms complexes mainly with oxo- or hydroxo-ligands with a tetrahedron configuration. Cr(VI) may be present in aqueous solutions as chromate ( $\text{CrO}_4^{2-}$ ), dichromate ( $\text{Cr}_2\text{O}_7^{2-}$ ), hydrogen chromate ( $\text{HCrO}_4^-$ ), dihydrogen chromate (chromic acid,  $\text{H}_2\text{CrO}_4$ ), hydrogen dichromate ( $\text{HCr}_2\text{O}_7^-$ ), trichromate ( $\text{Cr}_3\text{O}_{10}^{3-}$ ), and tetrachromate ( $\text{Cr}_4\text{O}_{13}^{2-}$ ) (Figure 1). The last three ions have been detected only in solutions of  $\text{pHCrpmol l}^{-1}$ . Thermodynamically, the aqueous equilibria are as in reactions [VI]–[VIII]:

**Table 2** Representative chromium compounds and their formal oxidation states and geometry

Oxidation state	Coordination number	Geometry	Compound

**Figure 1** Calculated distribution of inorganic Cr(III) species as a function of pH (solution in equilibrium with  $\text{Cr(OH)}_3$  precipitate).

**Figure 2** Calculated distribution of inorganic Cr(VI) species as a function of pH for a total concentration of  $10^{-6} \text{ mol l}^{-1}$ .

The distribution of these species with pH is shown in Figure 2.

Three pH regions may be distinguished for Cr(VI) species:

1. pH 0, where  $\text{H}_2\text{CrO}_4$  is a significant species;
2. pH 2–6, where  $\text{HCrO}_4^-$  and  $\text{Cr}_2\text{O}_7^{2-}$  occur together; and
3. pH > 9, where  $\text{CrO}_4^{2-}$  predominates.

In studies with various cell systems, starting with chromate, Cr(VI) has been shown to be present as an intermediate. It was found also in the presence of naturally occurring organic matter such as humus. The concentration of dichromate ( $\text{Cr}_2\text{O}_7^{2-}$ ) is negligible for total Cr(VI) concentrations below  $10^{-3} \text{ mol l}^{-1}$  over the whole pH range.

The interest in determining the concentration of the specific chemical forms of chromium rather than only its total concentration is the fact that the chemical forms have a profound effect on its mobility, bioavailability, and toxicity. Of the two oxidation states found in nature, trivalent and hexavalent, the former is relatively benign and the latter toxic.

Most organochromium compounds are not very stable and undergo hydrolysis and/or protolysis in the presence of water or even decompose in the presence of air. Because of their instability these species do not accumulate in the environment; however, they may play a role in some transport phenomena and metabolic pathways as transient species. The determination of such species in environmental or biological samples is hampered by their extremely low concentrations and the problem of their

differentiation from chromium physically sorbed onto organic species.

## Areas of Special Interest

In view of the different behavior of chromium species with respect to mobility, bioavailability, and toxicity, and in order to follow the pathways for interconversion both in the environment and in biological systems, it is increasingly important to monitor the concentration of the individual chemical species as well as the total concentration of chromium.

## Health Considerations and Occupational Monitoring

Cr(III) is held to be essential for human and animal nutrition, necessary for the maintenance of glucose, lipid, and protein metabolism, and is therefore used as a dietary supplement mostly in the form of its picolinate or nicotinate. Trivalent chromium is poorly absorbed principally because, unless heavily complexed, it will precipitate under most physiological pH conditions. Whilst Cr(III) compounds appear to be able to produce genetic effects with purified nucleic acids or cell nuclei, there is generally no such activity in intact cellular systems due to the relatively poor ability of Cr(III) to cross cell membranes.

In contrast, hexavalent chromium species, predominantly chromate at physiological pH, behave very differently and are toxic for bacteria, plants, and animals. Primary effects are related to the oxidative nature of Cr(VI), which manifests itself in irritation of the skin and the mucous membranes and allergic effects on lung and bronchia. Cr(VI) that survives reduction by body fluids is rapidly taken up by the

erythrocytes and lymphocytes penetrating the cell membrane via a general nonselective anion transport channel. In the cell nucleus, chromate can oxidatively damage genetically important components leading to DNA damage, reverse mutation, forward mutation, sister chromatid exchange, chromosomal aberrations, cell transformation, and alterations in mitotic cell cycle. Evidence is gathered that the ability of body fluids and long-lived nontarget cells to reduce Cr(VI) greatly reduces its potential toxicity.

The working group of the International Agency for Research on Cancer (IARC, France) concluded that there is sufficient evidence in humans for the carcinogenicity of Cr(VI) compounds as encountered in the chromate production, chromium pigment production, and chromium plating industries, and that there is inadequate evidence in humans for the carcinogenicity of metallic chromium and of Cr(III) compounds. Therefore, the major concern is in reducing and controlling the exposure to Cr(VI) for workers in industries handling chromium compounds as well as those being exposed by secondary products, e.g., welding fumes. However, there is no scope for chromium speciation in biological monitoring as all Cr(VI) in the body is converted to Cr(III) before it is excreted.

### Biological Monitoring

The effects of chromium on glucose metabolism have been studied extensively in both animals and man since the initial suggestion that a chromium compound in brewer's yeast influences glucose control. However, most of the findings were based on concentrations greatly influenced by contamination or lack of selectivity (e.g., atomic absorption spectrometry (AAS) with continuum source background correction; results obtained with such techniques should be questioned). Interpretation of the data on the effects of chromium on lipid and glucose metabolism is therefore difficult and the organic compound assumed to be the biologically active form of chromium has not yet been characterized and consequently is not available for supplementation studies. In addition, there is increasing evidence for the suggestion that the existence of the link between chromium and the glucose tolerance factor (Cr-GTF) is doubtful, and that earlier findings indicating the existence of the Cr-GTF complex have been heavily influenced by contamination.

The concentration of chromium in serum of unexposed healthy individuals is  $\sim 0.2 \mu\text{g l}^{-1}$ , i.e., 5000 times lower than that of zinc and copper. The interest for speciation of chromium in serum was initiated by the finding of extremely high chromium

levels (25–50 times that of healthy individuals) in the serum of dialysis patients as compared to healthy persons due to irreversible take-up from impurities of the dialysate. In order to follow biochemical processes involving the element, it is necessary to know the chromium-containing species. Because the time that is needed for classical ion-exchange procedures is so long, such that denaturation of the proteins occurs, it is necessary to perform these separations on a fast protein liquid chromatography system. The tedious workload to determine the very low concentrations in the various fractions and the immense hazards of contaminating with exogenous chromium can be partly overcome by the use of *in vitro* and *in vivo* labeled  $^{51}\text{Cr}$  plasma reducing the detection of the element to a simple radioactivity measurement. With the help of such methods chromium was found to be mainly bound to transferrin (85%) and to a lesser extent to albumin (8%) and other components (6%).

### Environmental Monitoring

Chromium enters the environment as a result of effluent discharge from steel works, electroplating, tanning industries, timber treatment, oxidative dyeing, chemical industries, and cooling water towers. The metal may also enter drinking water supply systems from the corrosion inhibitors used in water pipes and containers or by contamination of the underground water from sanitary land fill leaching. In view of the differences between the chromium species, chromium speciation rather than chromium total concentration has to be considered in pollution control and environmental risk assessment studies. Special attention has to be paid to industrial effluents, waste disposal, and sewage sludge deposition.

Tannery wastes usually contain high chromium concentrations (1–5%). Historical references to the antiquated, and virtually obsolete, two-bath chrome-tanning process, which uses Cr(VI), and the possibility of chromate pigments in finishing, have frequently resulted in confusion and exaggerated fears of tannery waste being hazardous from Cr(VI) contamination. Cr(VI) is readily reduced to Cr(III) in low-pH, organic-matter environments. Furthermore, Cr(VI) is not a tanning agent or otherwise useful material in modern tanning processes. On the other hand, due to the progressive exhaustion of landfills, land disposal of such sludge is increasingly attractive for economic as well as logistic reasons. However, chromium could affect metabolism and/or accumulate in living organisms. Furthermore, unavoidable oxidation of Cr(III) to more soluble and toxic species could cause groundwater pollution. Analytical interest in this field is devoted both to the control of such

waste disposals and to the development of less polluting processes, including recycling of the chromium.

### Aquatic and Marine Environment

Chromium is present in natural water systems in two thermodynamically stable oxidation states, Cr(III) and Cr(VI), depending on the redox conditions. Cr(VI) is often mistakenly referred to as a powerful oxidant in seawater, when, in fact, at pH 8.1 it has a redox potential lower than that of seawater. While thermodynamic calculations indicated that in fresh water chromium should exist almost exclusively as Cr(VI), experimental results differ significantly from prediction. Although the chemistry of chromium is understood in principle, it is strongly influenced by reactions that are kinetically slow, such as the oxidation of Cr(III) in seawater by oxygen. The Cr(III) ion is readily hydrolyzed and binds strongly to particles and organic material. Because Cr(III) is rapidly scavenged by particles, it is mainly in particulate form.

Adsorption on manganese oxide, followed by oxidation at the surface, helps considerably to convert Cr(III) into the thermodynamically stable Cr(VI). However, because of the low concentration of suspended  $\text{MnO}_2$  in the oceans, it is not clear whether this catalyzed oxidation is quantitatively more important than the direct oxidation by dissolved oxygen. Thus, chemical speciation of chromium in seawater is still an important issue in marine chemistry.

The concentrations of dissolved trace metals in interstitial waters of marine sediments often exceed predicted concentrations based on the solubility products of the most likely mineral phase. Complexes with organic matter having the general characteristics of humic substances with intermediate polarity may explain the observed excess solubility. Between 23% and 55% of the total, Cr in the interstitial water was found to be bound to organic material. It is assumed that the driving force behind this complex formation is the large crystal field stabilization energy associated with the formation of organic coordination complexes. These complexes may be an important factor in increasing the solubility of chromium and thus allowing its transport to the overlying water column. The trivalent chromium-organic matter association is so stable that it can be found even in the oxidizing water column.

While complexation/dissociation of chromium and natural organics has been postulated very often to explain data otherwise not in agreement with thermodynamic model calculations, there is a lack of direct evidence of its significance. Advances in understanding the biogeochemistry of chromium,

therefore, depend on the accurate determination of chromium species and the kinetics of their inter-conversion.

In conclusion, it can be stated that the valence-state distribution of dissolved chromium in natural waters will depend on the following important factors:

1. the oxygen content and redox potential of the water;
2. the presence of dissolved or particulate organic matter; and
3. the presence of suspended inorganic matter.

Samples for speciation studies, therefore, should be characterized accordingly with additional measurements of pH,  $pE$ , suspended inorganic matter, organic material, and oxygen content.

### Soil

The biomethylation of metals and metalloids in soils and sediments appears to be a widespread phenomenon. Owing to their altered physical properties like volatility and lipid solubility, the methylated compounds are important in the mobilization, transport, and bioaccumulation of trace elements in the environment. The methylation of Cr(II) by methylcobalamine appears to proceed by a homolytic pathway involving the transfer of a methyl radical.  $\text{CH}_3\text{Cr}(\text{H}_2\text{O}_3)^{2+}$  is the product of this reaction, but is rapidly cleaved under acidic conditions to give methane and Cr(III).

Generally, interest in the speciation of chromium in soil is to gain insights into mechanisms responsible for the mobility and bioavailability of the element. Therefore, the parameters under investigation are chromium solubility and its oxidation state, which are related to the bioavailability and toxicity. Because of its low mobility, landfill disposals of Cr(III) would not present a pollution problem, but in case oxidation of Cr(III) to Cr(VI) occurs it can be more serious. The migration of chromium is determined by the competition between complexation, dissolution/precipitation, redox processes, and adsorption/desorption mechanisms. Cr(III) will migrate under acidic conditions and/or if present as dissolved organic matter complex. Hexavalent chromium generally migrates more rapidly but its mobility is inhibited in presence of Fe(II) and high concentrations of organic matter and when sorption processes are favored at low pH. Numerous separation schemes are in use, based on the leaching of soil with different solvent and buffer systems. Generally, these 'procedural speciation techniques' lack in standardization and comparability, and interpretation of results is

not straightforward. In an effort to improve this situation, the European Community Bureau of Reference (BCR) has promoted the evaluation, improvement, and standardization of a sequential three-stage extraction scheme that today has been characterized for a variety of sample matrices.

## Methods for the Determination of Chromium Species

The variety of methods for the determination of chromium species may be classified into two fundamental categories: species-selective, direct measurements and nonselective detection combined with species-selective separation methods. In the case of chromium, two strategies can be distinguished for the later approach: simultaneous separation and determination of both species or determination of one species and the total chromium concentration, obtaining the result for the second species by calculation 'through difference'. Since such an indirect approach involves some risk due to cumulative errors, it is nowadays avoided whenever possible. Such and other problems can often be prevented by techniques combining a selective separation technique online with a sensitive detection technique, creating a very powerful 'hyphenated technique'.

### Special Considerations in Sample Handling

The sampling, sample pretreatment, and storage of samples are the most critical stages in any procedure for trace metal analysis but even more so for speciation analysis. These critical steps should be performed either directly by, or under the supervision of, qualified personnel. The requirements for the determination of chromium speciation depend strongly on the type of sample and the concentration range. The main concerns are analyte loss during sample preparation, contamination, and species transformation. Generally, attention should be paid to the selection of tools and containers for sampling and sample pretreatment. Tools such as knives, mixers, homogenators, or mills made from stainless steel, most often containing chromium, should be avoided and replaced by tools made from polymeric materials, quartz, and titanium. Colored polymeric materials, such as screw-caps for bottles, dispensers, and pipette tips are suspect and should be controlled for chromium contamination.

Most stringent requirements on sampling, sample pretreatment, and sample storage have to be fulfilled in the analysis of biological materials, because physiological concentrations are in the low microgram per liter or submicrogram per liter level.

Disposable steel needles used widely in medical practice for drawing of blood samples cannot be used for sampling blood intended for trace metal analysis. Contamination of blood samples by such needles can exceed the actual level of chromium in the sample by a factor of 100–1000. In case liquid chromatography (LC) is used for separation of species, the system inherent contamination has to be taken in account, when using high-performance liquid chromatography (HPLC) equipment (pumps, valves, columns, capillaries) made from stainless steel.

The problems of contamination obviously extend to any sample pretreatment procedures, which, therefore, should be reduced to the absolute minimum for ultratrace determinations. If sample pretreatment is necessary or considered appropriate, great care must be taken to ensure that chromium from the reagents or containers used, or indeed from the environment, does not contaminate the sample and invalidate the results.

In the field of water analysis the interest is in differentiation between soluble and particulate chromium as well as between the two main oxidation states. The system Cr(III)/Cr(VI) is subject to redox reactions, especially in the presence of oxygen and/or organic materials. As soon as possible after its collection, water samples should be filtered if metal speciation is to be studied in order to avoid any remobilization of metals bound or sorbed to particulate matter. While pressure filtration offers advantages in terms of speed of filtration it may contribute to enhanced soluble organic matter by rupture of phytoplankton cells.

Collection of particulate matter from atmospheric air or aerosols being present in the workplace environment for subsequent species determination needs special care. Variable amounts of Cr(VI) can be reduced by filter materials like paper or cellulose or in the presence of materials co-collected on the filter. Poly(vinyl chloride) filters should be used and samples should be either stabilized by preconditioning of the filters or immediately after collection.

### Storage of Samples

For speciation studies it is very important that the analyses be performed as soon as possible after collection. If samples have to be stored, the risk of Cr(VI) reduction, especially in the presence of organic material under acidic conditions, has to be considered. Cr(VI) losses in the range of 15–20% have been observed during the first day after sampling. In contrast, Cr(III) is remarkably susceptible to oxidation in alkaline medium. Only in neutral solutions are the different chromium species comparatively resistant to redox reactions, partly because

of slow kinetics and also the oxidation potential of the Cr(III)/Cr(VI) couple in such solutions. The medium oxidation potential under neutral conditions relatively stabilizes the Cr(III)/Cr(VI) couple both against oxidation and reduction. Consequently, samples should be stored without acidification. Unfortunately, Cr(III) shows the highest instability at neutral pH with respect to losses by sorption on container walls, particularly in polyethylene containers, where losses up to 25% have been observed after 15 days of contact. If sample storage cannot be avoided, then the best stability of the species distribution is obtained in a buffer solution containing  $50 \text{ mmol l}^{-1}$   $\text{HCO}_3^-/\text{H}_2\text{CO}_3$  in polytetrafluoroethylene bottles if kept at  $5^\circ\text{C}$  under a  $\text{CO}_2$  blanket.

In order to reduce the possibilities for species transformation between sampling and analysis some researchers have proposed to perform the separation onsite by using short chromatographic columns operated under low-pressure conditions (flow injection, FI) as collection devices in the field. Rather than transporting the water samples back to the laboratory, the loaded columns will be used instead. It was demonstrated that the column variability is in the range of single-column replicates, allowing for the establishment of convenient, versatile, and easy to use methodology, with built-in preconcentration ready for automation.

### Species-Selective Direct Techniques

For the direct speciation analysis of chromium traces only a few techniques are available.

**UV-visible spectrophotometry** UV-visible spectrophotometry is a well-established technique for the selective determination of Cr(VI) with good detection power. The standard method for the selective determination of Cr(VI) is based on the formation of a red-violet colored complex with 1,5-diphenylcarbazide under acidic conditions, which can be detected spectrophotometrically at 540 nm. In order to achieve good reproducibility, several conditions such as temperature or amount of reagent and acids must be kept strictly constant. The molar absorption coefficient is from  $3.0 \times 10^4$  to  $8.0 \times 10^4$ , fairly high, allowing detection limits of  $\sim 5 \mu\text{g l}^{-1}$  under optimized conditions. The complex is very stable (less than 2% signal reduction over 90 min) and only a few ions like Mo(VI), Cu(II), Mn(II), Fe(III), and Hg interfere, but only at high concentrations. Some of these interfering ions can be masked either with phosphate or ethylenediamine-tetraacetic acid (EDTA) or kinetically differentiated. The main problem in its application is the acidic

conditions needed for complex formation with the potential risk of reducing Cr(VI) especially in the presence of organic materials, normally present in samples like natural or waste water. In general, spectrophotometric determinations in sample solutions that are originally colored is problematical.

In order to determine total chromium, Cr(III) has to be oxidized either during sample pretreatment or, more elegantly, online with Ce(IV) using a FI manifold. The methods of oxidizing chromium to the required state and of destroying the excess of oxidizing agent are of critical importance for the overall performance of the method. In the conventional analytical procedure an excess of permanganate has to be decomposed by reduction with azide or by precipitation as hydrous  $\text{MnO}_2$ , while an excess of peroxydisulfate can be decomposed by boiling the solution or by reduction with azide. Ce(IV) can be used for online oxidation; however, the blank introduced with this reagent seriously degrades the detection limit of this approach and the online method is less tolerant against interferents such as Fe(III), Mo(VI), Mn(II), or Cu(II). Other spectrophotometric methods based on complex formation with Cr(III) are less selective and sensitive and therefore are of not much importance.

**Chemiluminescence** Cr(III) can be selectively determined by chemiluminescence. The detection is based on the oxidation of luminol by  $\text{H}_2\text{O}_2$  catalyzed by the presence of small concentrations of Cr(III). The reaction is highly selective for Cr(III), Cr(VI) does not catalyze the luminol reaction. Interferences from other metal ions can be eliminated by the addition of a chelating compound, such as EDTA, which forms complexes with the interferents, thereby inactivating them as catalysts. Because of the kinetic inertness of Cr(III), chromium complexes do not form at room temperature during the analysis time. The whole procedure can be easily automated by the use of FI systems, allowing high sample throughput for routine analysis. The high detection power of this method allows the determination in environmental samples such as surface waters or seawater or even biological samples.

**Electrochemical methods (polarography and voltammetry)** The electrochemical behavior of Cr(III) and Cr(VI) is significantly different, allowing the species-selective determination by polarographic and voltammetric techniques. Cr(VI) is electrochemically active over the entire pH range; hence, a medium pH can be selected for the measurements, thus effectively protecting samples from undergoing redox reactions during the analytical procedure. Direct

differential pulse polarography provides detection limits of  $\sim 30 \mu\text{g l}^{-1}$ , this detection limit can be substantially improved by electrochemical preconcentration. Cathodic stripping voltammetry preceded by adsorptive collection of a complex of Cr(III) with, e.g., diethylenetriamine pentaacetic acid or Cr(VI) with diphenylcarbazide on a hanging Hg drop electrode provides the necessary sensitivity for natural water samples including seawater. Other techniques like amperometry or potentiometry are mainly applied to automated effluent monitoring and process control.

**High-resolution X-ray spectroscopy** High-resolution X-ray spectroscopy can be used for the direct speciation of chromium in solid samples, such as air particulates, welding dust, and soil. These techniques use the effect that the chemical environment of the target analyte chromium is producing a chemical shift that is different for Cr(III) and Cr(VI) and can be observed in both emission and absorption X-ray spectra. Applications have been described for using the shift on the Cr  $K_{\alpha 1}$  and  $K_{\alpha 2}$  emission lines (X-ray fluorescence, XRF), the shift on the L-transitions that can be excited by low-energy electrons ('soft X-ray') or the shift in the profile of the near-edge absorption spectra. Using such techniques in combination with chemometric data evaluation, the distribution of chromium species in solid samples can be measured quantitatively in cases where the total chromium concentration is sufficiently high.

### Speciation Techniques Based on Separation of Chromium Species

Speciation techniques based on the separation of different chromium species before detection have the advantage of making possible the combination of a highly selective technique with a highly sensitive detection technique. While often the detection power of the combined technique can even be increased by preconcentration, a serious drawback is the complex and time-consuming sample pretreatment, based on solvent extraction, co-precipitation, electrochemical separation, ion exchange, solid-phase extraction, or selective volatilization. It is also apparent that any separation-detection method must not alter the initial species profile in the sample undergoing analysis; that is, the results of the analytical method must accurately and correctly represent what was present in the initial sample before it was touched. Therefore, in general, more direct methods are in favor of more complex methods, where multiple steps are a potential risk with respect to contamination and alteration

of the original species distribution. If multiple steps cannot be avoided, their integration into a single combined 'hyphenated technique' has the advantage of improved reproducibility through the exact control of parameters and the speed of analysis, and the use of a 'closed system' reducing the risk of contamination.

The determination of chromium can be performed by a great number of physicochemical methods, with different detection powers, working range, and application field. Here, only those techniques that have found more general applications in different fields can be briefly discussed. The selection of a method for a special analytical task is not only dependent on the detection power and other performance characteristics of the technique, but is highly dependent on the sample constitution, the required sample pretreatment and means of sample introduction, and, last but not least, on its availability (Table 3).

Most of the mentioned analytical techniques can be coupled with separation procedures, either to enhance their detection limits by preconcentration, or to enhance their selectivity by separation from interferences or to allow for species selective determination. Especially for the last case, online coupling of separation techniques such as gas chromatography (GC), HPLC or FI techniques, with some of the detection techniques named in the above table are very attractive.

**Atomic absorption spectrometry** AAS is historically the most widely used technique for trace element determination in general and for the analysis of chromium in particular.

**Flame AAS (FAAS)** Chromium can be determined by FAAS using both air-acetylene flame and a nitrous oxide-acetylene flame, giving no flame background problems in the wavelength range used for determination. A large number of resonance lines of similar sensitivity are available, but for the majority of work the 357.9 nm line is used. The sensitivity and dynamic range of chromium determinations by FAAS are critically dependent on flame conditions and the observation zone. Using the air-acetylene flame, the reductive power of a fuel-rich flame is essential for effective atomization of chromium salts, giving a characteristic concentration of  $\sim 40\text{--}80 \mu\text{g l}^{-1}$ , depending on the aerosol transport efficiency of the nebulizer/burner system and the flame conditions, allowing precise determinations in the concentration range from 0.5 to  $\sim 10 \text{ mg l}^{-1}$ . Sensitivity for chromium using the air-acetylene flame is different for different chromium compounds with Cr(III) giving higher sensitivity than Cr(VI), the difference being

**Table 3** Various analytical techniques and their characteristics for the determination of chromium

Analytical method	Detection limit <sup>a</sup> ( $\mu\text{g l}^{-1}$ , 3 $\sigma$ )	Multi-element capability	Micromethod	Hyphenation	Sample types for direct sample introduction				Degree of interferences		
					Solution	Suspension	Solids		Mechanical, physical	Chemical	Spectral detection
NAA	5000	+	-	-	+	+	+		+	-	+
XRF	500	+	+	-	+	+	+		+	+	-
Flame-AAS	20-200	±	±	+	+	+	-		+	+	-
Polarography, DPP	10-50	+	-	+	+	+	-		+	+	-
Photometry	2-20	-	-	+	+	+	-		+	+	+
ICP-AES	1-5	+	-	+	+	+	LA, ETV, Arc		+	-	+
TXRF	0.2-1.0	+	+	-	+	+	-		+	+	+

ICP-MS	0.02-0.05	+	-	+	+	+	LA, ETV, Arc		+	-	+

<sup>a</sup> All detection limits are mean instrumental detection limits, which can be seriously degraded in the presence of a complex matrix.

most pronounced in fuel-rich air-acetylene flames and also at the observation height, giving the best sensitivity.

Iron and nickel cause severe depression of the atomic absorption signal from the air-acetylene flame, which can be attributed to the formation of refractory oxides. Several releasing agents such as ammonium chloride or fluoride, hydroxylamine hydrochloride, sodium sulfate, and others have been used to eliminate these interferences. Removal of interferences occurs in most instances through the introduction of a new dominating influence on the flame reactions controlling the atom formation process despite the presence of the original interferent. Many of these interferences decrease in hotter flames and in hotter regions of flames, and can be suppressed or even eliminated by the use of the nitrous oxide-acetylene flame but only at the expense of reduced sensitivity (about one-third) in comparison to the air-acetylene flame.

**Electrothermal atomization AAS (ETAAS)** ETAAS using the graphite furnace has been clearly the most common technique for the determination of chromium in the low trace and ultratrace range especially encountered with environmental and biological materials. Despite its broad application, the determination of ultratrace levels of chromium by ETAAS is not without problems. The accuracy of such determinations is determined, amongst other factors, by the precise correction of nonspecific absorption of light by concomitant compounds. Owing to the low intensity of the deuterium lamp at 357.9 nm, background absorption and emission produced by matrix components cannot be efficiently corrected when using this type of background correction. This situation improves when using Zeeman-effect background correction systems that is able to compensate for high absorbances, such as those produced by biological matrices, and is therefore the technique to be used in this field.

Standard procedures to overcome matrix interferences such as the use of platform atomization together with the use of matrix modifiers are only in part applicable to the ultratrace determination of chromium in biological samples. Matrix modifiers normally used such as palladium and magnesium are often too highly contaminated, and therefore cannot be used without degrading the detection limit, which is  $\sim 0.1 \mu\text{g l}^{-1}$ . Chromium interacts with carbon, forming carbides, a reaction that is responsible for chromium retention in the graphite tube, giving rise to tailing peaks and carry over. In general, high heating rates and atomization from a pyrolytic graphite coated surface will give the best performance. In

the case of transversely heated graphite tubes, such conditions can also be attained by using platform atomization.

The maximum charring temperature that can be used for chromium in aqueous solution is  $\sim 1200^{\circ}\text{C}$ . At this temperature, most if not the whole organic matrix is removed but a large proportion of the major inorganic salts present in biological samples remain even after prolonged charring times, giving rise to a substantial background signal during the atomization stage. Addition of magnesium nitrate as a matrix modifier extends the possible charring temperature to  $1600^{\circ}\text{C}$ , ensuring more complete removal of inorganic salts.

By using chelating compounds such as trifluoroacetylacetone as a modifier in combination with the graphite tube as a programmable thermal reactor, species-specific determination can be realized by ETAAS. The method is based on the formation of a volatile Cr(III) complex that is lost from the heated graphite tube prior to atomization, thus only detecting Cr(VI).

**Atomic emission spectrometry** The atomic emission spectrometry (AES) determination of chromium using the inductively coupled plasma (ICP) as the excitation source is a well-established method. ICP-AES in its conventional form, using a pneumatic nebulizer for sample introduction, has become the working horse for analyzing solutions especially in environmental analytical laboratories. Sample pretreatment is generally the same as for AAS, calling for leaching, dissolution/digestion as the main procedure for most solid samples while liquid samples, such as water or beverages, can be introduced directly in many instances.

Being a multielement technique, ICP-AES exhibits detection limits for chromium in the range of  $1\text{--}5\text{ }\mu\text{g l}^{-1}$ . Although chemical interferences are generally uncommon in ICP-AES, there are some restrictions in the total salt concentrations, which can be introduced into the plasma using conventional nebulization techniques, calling for further dilution. Moreover, detection limits can be seriously degraded by spectral interferences, much more common in ICP-AES than in AAS. Apart from metallurgical applications, sensitivity is satisfactory for the analysis of most environmental samples (dust, soil, sediments) and some biological materials (plants, foods), with the exception of more demanding samples like body fluids or tissues. Other sources for AES such as flame, arc, spark, glow-discharge source, direct-current plasma, microwave-induced plasma have been applied for the determination of chromium in special cases.

**Mass spectrometry** Mass spectrometry (MS) using the ICP as the ion source shares most of the advantages of ICP-AES, namely a stable ICP source with the additional feature of 10–100 times improved detection limits. For mass spectrometric detection of chromium most often the main isotope  $^{52}\text{Cr}$  is used, since  $^{53}\text{Cr}$  and  $^{54}\text{Cr}$  are overlapped by iron isotopes and  $^{50}\text{Cr}$  by a titanium isotope. Chromium isotopes are in an advantageous mass range in terms of sensitivity, allowing detection limits well below  $0.1\text{ }\mu\text{g l}^{-1}$  under optimized conditions, thereby closely reaching or even surpassing the detection power of GFAAS. The high detection power together with the multielement capability of ICP-MS makes this technique very suitable for environmental and biological samples. However, determinations below a few micrograms per liter are hampered by isobaric interference of the  $^{52}\text{Cr}$  by polyatomic ions between argon (the plasma gas) and nitrogen, oxygen and carbon, especially with samples rich in organic compounds or using organic solvents. These interferences can be overcome by either high-resolution ICP-MS using sector-field technology or by quadrupole ICP-MS in combination with chemical resolution provided by reaction/collision cell technology.

An especially attractive feature of ICP-MS is the possibility of using isotope dilution as a calibration strategy, enhancing the accuracy of measurements significantly. In its special form of speciated isotope dilution (SIDMS) this method can even correct for some species transformation during analysis. For this purpose, SIDMS is using the concept of spiking the sample with known amounts of enriched isotopes that have been chemically converted into the same forms of the species to be analyzed. The isotopic spike for each species has a unique isotopic enrichment. In the case of chromium two isotopic spikes, Cr(VI) enriched in  $^{53}\text{Cr}$  and Cr(III) enriched in  $^{50}\text{Cr}$ , are prepared for the simultaneous determination of Cr(III) and Cr(VI). Environmental samples containing Cr species are spiked with both  $^{53}\text{Cr(VI)}$  and  $^{50}\text{Cr(III)}$ . The species are separated at the end of the manipulation by means of chromatography and different isotope ratios are measured. In contrast to 'classical' chromatography, which provides a snapshot recording the state of affairs at the end of the manipulation, any interconversions that occur after spiking are traceable by SIDMS and can be quantitatively corrected by monitoring isotopes in each species. However, as with any isotope dilution method, accurate determinations can only be obtained when the spike behaves in every aspect like the species originally present and is 'equilibrated' with it before the determination step. This prerequisite is not easy to fulfill in some real samples, where the

freshly added Cr(III) spike behaves differently from the present Cr(III), which in a precipitated form is subjected to aging effects.

Online coupling of ICP-MS with LC is relatively straightforward. The separation power required to separate the two oxidation states of chromium is not very high, so that even some short columns operated under low- or medium-pressure conditions may be useful. Different chromatographic techniques such as suppressed ion chromatography, chelation ion chromatography, mixed anion/cation exchange chromatography, or reversed-phase chromatography of dithiocarbamates have been used for this purpose with success.

**X-ray fluorescence** XRF is one of the longest established techniques for trace elemental analysis. While XRF is not a very sensitive technique, its main advantages are the capability for direct solid sample analysis combined with multielement determinations. While sample pretreatment of solids can be substantially reduced or even omitted in some cases, perfect matching between standards and samples is required for accurate results, because of severe matrix effects. The main application field of XRF is, therefore, the analysis of solid materials, such as metallurgical and geological samples, where solid standards are readily available. Liquid samples can be analyzed either directly in special cells or by using preconcentration techniques with solid sorbents, which can be directly analyzed after sample loading. More modern methods, like total-reflection X-ray fluorescence, which is a multielement technique mainly for solutions, or particle-induced X-ray emission, which is a micromethod with some spatial resolution, have found limited application in some special areas. For speciation purposes, species separation has to be carried out in front in an offline mode.

### Radiochemical methods

**Neutron activation analysis** Thermal neutron activation of Cr leads to two radionuclides of which the short-lived radionuclide  $^{55}\text{Cr}$  has a low abundance compared to the parent isotope (2.36%), a relatively small cross-section for formation (0.36 barn), and, most significantly, it is almost a pure  $\beta$ -emitter and emits very few  $\gamma$ -rays (0.043%). The lower limit of detection using this radionuclide is very high and measurement of chromium by neutron activation analysis (NAA) is carried out using the long-lived radionuclide  $^{51}\text{Cr}$ . The half-life of  $^{51}\text{Cr}$  is within a range of 27.8 days, allowing sufficient time for sample manipulations.

In order to obtain high sensitivity the sample should be irradiated at high fluxes for long periods of

time (several days or at least 10–20 h). With these long irradiation times liquid samples will suffer considerable radiolysis, leading to the formation of large amounts of gases, which are likely to lead to explosion of the irradiation ampoule. Hence, a solid sample should be used and, rather than drying the liquid sample, it is preferable to preconcentrate the trace elements by co-precipitation. The best co-precipitants for NAA will be compounds that have small thermal neutron absorption cross-sections and which do not form  $\gamma$ -emitting radioisotopes on neutron absorption.

Sensitivity can further be increased by preconcentration following the radiation (and appropriate decay time) before detection with the advantage that contamination during these steps can be ignored. Whilst excellent results have been achieved with such procedures even for ultratrace determinations of chromium in biological material, the expensive instrumentation required precludes the use of this method for routine analysis, but it does play a vital role in cross-validation.

**Radioactive tracer techniques** Chromium-51 can be used as a radioactive tracer in isotope dilution analysis. After adding known amounts of the tracer to the sample, chromium is separated by a substoichiometric procedure. Under the assumption that the isotopic ratio for the spiked sample will not be changed by the separation procedure, the original chromium concentration can be calculated from the activity ratios measured. This assumption, however, is only valid if both the original chromium and the added chromium tracer have the same oxidation state and are homogeneously distributed. The whole sample preparation procedure has to be designed in order to fulfill these requirements.

### Separation Techniques

**Separation by extraction** Most of the methods of selective extraction are based on the extraction of Cr(VI) into organic solvents using ion pairs either with the anion of a mineral acid, or by some ion-pairing reagents such as trioctylphosphine oxide, trioctylamine, or Aliquat-336. Other methods are based on complex formation with chelating agents such as dithiocarbamates or liquid ion-exchangers such as Amberlite LA-2. The crucial point of this principle is the risk of co-extraction of Cr(III) complexes initially present in the sample. Another risk with this type of separation is the use of acidic media, which is often needed for the quantitative extraction of Cr(VI) with many reagents but favors reduction of Cr(VI) especially in the presence of organic material.

Preconcentration methods based on complex formation with Cr(III) have not been applied so widely, owing to the inert nature of hydrated Cr(III) species. Consequently, Cr(III) is normally obtained by difference after the determination of total chromium and Cr(VI). Especially in those cases, where Cr(III) is only a small part of the total chromium present in the sample, e.g., seawater, determination by difference may not be adequate, due to the large uncertainties introduced by such a calculation.

For the direct preconcentration and separation of Cr(III), complex formation has to be accelerated with most of the ligands available. The simplest method for the enhancement of the complexation rate is to heat the sample solution. Efforts have been made to decrease the reaction time and temperature required by the addition of large amounts of reagents that have catalytic effects on the ligand-exchange reactions. Reagents such as fluoride, benzoate, and dodecyl sulfate have been used for this purpose. Quinolin-8-ol was used as a complexation reagent, reacting more rapidly than others with Cr(III) and having the advantage of a good selectivity for Cr(III) and no reducing ability.

**Separation by co-precipitation** Co-precipitation as a method for species-selective separation offers a high preconcentration factor of  $10^2$ – $10^3$  by using only standard laboratory equipment. Working at pH levels between 6 and 9, the risk of influencing the redox equilibrium is comparatively small. The hydroxides of Fe(III), Al(III), Ti(III), or others have been used as carriers for the co-precipitation of Cr(III) in accordance with a suitable detection technique. Often, the high amount of carrier used must be removed prior to the determination of chromium to avoid serious interference problems. Partial adsorption of Cr(VI) onto the precipitate can reduce the selectivity of the approach.

**Separation by liquid chromatography, ion-exchange, sorption, and solid-sorbent extraction** The use of ion-exchange methods for chromium speciation is based on the assumption that Cr(III) definitely forms cations so that anions, collected on a column, are considered as Cr(VI) by definition. However, this premise does not hold for Cr(III) complexes, which may be present in an anionic form. Further, real samples, such as river water, may contain negatively charged colloids, including humic substances, kaolin, hydrated silica, and their mixtures with hydrated iron(III) oxide, which may sorb Cr(III) and be partly retained on the resins.

Problems inherent in manual sample manipulation have been overcome, at least, in part, by hyphenated

techniques such as LC or FI coupled to photometric, electrochemical, or spectrometric detection techniques. Reversed-phase  $C_{18}$  silica gel has been used for the chromatographic separation of chromium species, which often results in inadequate sensitivity for trace concentrations of chromium in real samples because of low sample loading. In order to achieve adequate detection limits for trace determinations some preconcentration, preferentially on-column, has to be performed. Preconcentration of Cr(III) is not as straightforward as for Cr(VI) because the inertness of Cr(III) hinders efficient complexation resulting in poor sensitivity, low sampling frequency, and incomplete recovery.

A number of advantages, in addition to automated sample handling, sample manipulation in a closed system, and miniaturization, emerge from the application of flow techniques such as FI or sequential injection (SI) to classical chemical procedures. A salient feature of these techniques is the well-known reproducibility of the processes involved, which allows for very short analysis times since it is not required to wait until equilibrium has been established. This last factor is particularly important because prolonged sample manipulation may affect the chromium species distribution significantly. When flow techniques are used for separation, the objective is to separate a single analyte or group of analytes from interfering sample components or matrices, often simultaneously achieving some degree of preconcentration and therefore gaining sensitivity at the expense of separation power. The FI/SI separation process is quite similar in this respect to batch filtration or solvent extraction procedures, and no chromatographic processes are involved, despite the fact that some chromatographic equipment like HPLC pumps and online columns might be used for this purpose. Different solid sorbents have been used for FI/SI preconcentration, such as chelating ion-exchangers, e.g., polydithiocarbamate, polyacrylamidoxime, polyhydroxamic acid, or iminodiacetate chelate resin, immobilized chelating reagents on solid supports such as quinoline-8-ol immobilized on controlled-pore glass, silica gel, or activated alumina. Activated alumina offers the principal possibility for preconcentration of both chromium species since it can function both as an anion exchanger and as a cation exchanger depending on the pH of the solution. Under acidic conditions alumina exhibits a high affinity for oxyanions whereas it strongly retains cations under basic conditions.

**Gas chromatography** Using trifluoroacetylacetone, Cr(III) can be converted into a volatile complex that can be separated from other similar metal complexes

by GC. Considerable sensitivity can be achieved by using the electron capture detector, microwave excitation, atomic absorption, or MS for its detection.

**Electrophoresis** Capillary electrophoresis (CE) has been successfully used to separate Cr(III) and Cr(VI) species in recent years. Detection was done by UV-photometry, chemiluminescence, or ICP-MS. The online coupling of CE and ICP-MS is often realized by using microflow nebulizers or by compensating the difference between the very low effluent flow rate from the CE capillary and the much higher uptake of conventional nebulizers with a make-up buffer flow. Flat bed electrophoresis can be used to separate high molecular weight compounds such as proteins. Element-selective detection can be achieved by scanning the chromatographic plates with laser ablation ICP-MS.

## Quality Assurance

Quality control and quality assurance have become a very important part of trace analysis, and analysts are requested not only to prove that their methods produce reliable results but they should also report the uncertainty coming with it. In general, two different approaches are available to discuss obtained results, either by comparing the results obtained by the method used against a reference method or by comparing the results for the analyzed samples against those for reference materials. Both approaches are extremely difficult to fulfill for speciation analysis, since both standard methods and certified reference materials (CRMs) are rare or even non-existing. Speciated isotope dilution analysis could in some cases play the role of a reference method, particularly if the already discussed prerequisite of a total equilibrium between spikes and originally present species can be guaranteed. Today, CRMs are only available for a very limited number of matrices, namely NIST 2108/2109 (aqueous solutions of pure Cr(III) and Cr(VI)), BCR 544 (both Cr(III) and Cr(VI) in lyophilized solution), BCR 545, which is certified for Cr(VI), and total leachable chromium in welding dust loaded on a filter, and DANREF Cement-1 and Cement-2, which are certified for their chromate content in cement.

### Overview of Aims and Scope – Philosophy of Clinical Analysis

Clinical laboratories have to be able to determine a wide range of analytes. These encompass a wide range: ions, small organic molecules, proteins, and lipids. Typically measurements are made on biological fluids. Most determinations are performed on plasma (or serum) the liquid fraction of blood, or urine; occasionally other fluids such as cerebrospinal fluid may be examined. While some of the measurements relate directly to pathology in the blood cells or plasma, many are markers of changes happening at the cellular level. Cell destruction releases intracellular contents, e.g., enzymes, tumors release products; cell dysfunction causes buildup or diminution of normal concentrations of molecules.

Analyses for some of the analytes are requested very frequently, often requiring a rapid turn-round

time (0.5–2 h). To meet this demand, high-capacity rapid-throughput analyzers have to be utilized. A different approach is the increasing availability of point of care testing, i.e., testing outside the laboratory.

Less frequent or more specialized assays are performed using one or other of the more usual armamentarium of analytical biochemistry such as chromatography and enzyme-based methods. Clinical laboratory testing is intended to enable a qualified individual to diagnose and monitor disease. A great number of different analytes are measured with this aim in mind. Some of the commonly determined analytes are relatively specific for a disease or are particularly useful for monitoring disease progression.

The clinical utility of a test is described by its sensitivity – the ability to detect the disease with no false negatives – and its specificity – the ability to avoid false positives in the nondiseased population. The ideal test detects all those with disease and does not include any of those without the disease. No test meets these criteria. Combinations of tests may yield better classification, termed efficiency, but rarely achieve 100% efficiency. Complicating this perspective is the fact that patients present at different stages of disease, also some clinical analytes may change in

### Overview of Aims and Scope – Philosophy of Clinical Analysis

Clinical laboratories have to be able to determine a wide range of analytes. These encompass a wide range: ions, small organic molecules, proteins, and lipids. Typically measurements are made on biological fluids. Most determinations are performed on plasma (or serum) the liquid fraction of blood, or urine; occasionally other fluids such as cerebrospinal fluid may be examined. While some of the measurements relate directly to pathology in the blood cells or plasma, many are markers of changes happening at the cellular level. Cell destruction releases intracellular contents, e.g., enzymes, tumors release products; cell dysfunction causes buildup or diminution of normal concentrations of molecules.

Analyses for some of the analytes are requested very frequently, often requiring a rapid turn-round

time (0.5–2 h). To meet this demand, high-capacity rapid-throughput analyzers have to be utilized. A different approach is the increasing availability of point of care testing, i.e., testing outside the laboratory.

Less frequent or more specialized assays are performed using one or other of the more usual armamentarium of analytical biochemistry such as chromatography and enzyme-based methods. Clinical laboratory testing is intended to enable a qualified individual to diagnose and monitor disease. A great number of different analytes are measured with this aim in mind. Some of the commonly determined analytes are relatively specific for a disease or are particularly useful for monitoring disease progression.

The clinical utility of a test is described by its sensitivity – the ability to detect the disease with no false negatives – and its specificity – the ability to avoid false positives in the nondiseased population. The ideal test detects all those with disease and does not include any of those without the disease. No test meets these criteria. Combinations of tests may yield better classification, termed efficiency, but rarely achieve 100% efficiency. Complicating this perspective is the fact that patients present at different stages of disease, also some clinical analytes may change in

**Table 1** Some common clinical analytes

Group name	Analytes (optional)	Matrix	Units	Useful in emergency	Indicative of
Urea and electrolytes	Urea	Serum or plasma	$\text{mmol l}^{-1}$	Yes	Kidney function
	(Creatinine)		$\mu\text{mol l}^{-1}$		Kidney function
	Sodium		$\text{mmol l}^{-1}$		Fluid and electrolyte balance
	Potassium		$\text{mmol l}^{-1}$		Potassium homeostasis
Liver function tests	(hydrogen carbonate)	Serum or plasma	$\text{mmol l}^{-1}$	No	Acid-base status
	(chloride)		$\text{mmol l}^{-1}$		Acid-base status
	Bilirubin		$\text{mmol l}^{-1}$		Liver obstruction
	Alanine transaminase		$\text{U l}^{-1}$		Liver damage
	Aspartate transaminase		$\text{U l}^{-1}$		
	Alkaline phosphatase ( $\gamma$ -glutamyl transpeptidase)		$\text{U l}^{-1}$ $\text{U l}^{-1}$		Liver obstruction
Bone chemistry	Calcium	Serum or plasma	$\text{mmol l}^{-1}$	Yes	Bone metabolism
	Albumin		$\text{g l}^{-1}$		Correct for $\text{Ca}^{2+}$ protein binding
	Phosphate		$\text{Mmol l}^{-1}$	No	Bone metabolism
	Alkaline phosphatase		$\text{U l}^{-1}$		Bone building cell activity
Cardiac markers	Troponin T (or I)	Serum or plasma	$\text{U l}^{-1}$	Possibly no	Indicators of heart attack after 12 h
	Creatine kinase				
Thyroid function test	Thyroxine	Serum or plasma	$\text{nmol l}^{-1}$	No	Thyroid function
	Triodo thyronine		$\text{nmol l}^{-1}$		
	Thyroid-stimulating hormone		$\text{U l}^{-1}$		
	Urate	Serum or plasma	$\text{mmol l}^{-1}$	No	Indicator of gout
	Creatinine clearance	Urine plus serum	$\text{ml min}^{-1}$	No	Indicator of kidney function
	Sodium	Urine	$\text{mmol}$	Yes	Indicator of circulating blood volume status
	Amino acids	Urine	$\text{mmol l}^{-1}$ and $\mu\text{mol l}^{-1}$	No	Inborn errors of metabolism
	Porphyrin	Serum, urine, or feces	$\mu\text{mol l}^{-1}$ or $\mu\text{mol day}^{-1}$	No	Inborn or acquired errors of metabolism

different diseases. This may be due to a primary change, i.e., directly due to the disease process or be secondary to a disease process, e.g., due to reduced metabolic clearance.

However, the use of suitable criteria enables decisions to be made as to the best analyte to measure or detect disease. For example, prostatic cancer may be detected by measuring prostate specific antigen, however, it may be raised in other conditions or be normal in the presence of cancer; the specificity and sensitivity while acceptable mandate the test be part

of a group of investigations. Lack of awareness of the performance characteristics of clinical analytes in detecting pathology is under-appreciated by professionals and patient knowledge is much worse. For the well-established tests (for example see **Table 1**) the specificity and sensitivity are typically poor but a particular test in combination with other tests and the clinical history is a useful indicator of disease. In the early 1970s this led to the concept of screening to detect occult disease. Experience showed this was not clinically useful or cost-effective and with the

modern selective multichannel analyzers the move is toward organ profiles, e.g., to detect bone diseases such as osteomalacia, bone malignancies, parathyroid adenoma, etc.

Clinical laboratories prioritize the turnaround of results. This is decided by clinical demand and analytical feasibility. Laboratories offer their full repertoire during the day and during the week and offer a more restricted service outside these times. However, the changes in healthcare are increasing demands on laboratories and there is more 24 h, 7 days a week availability of the test menu. Some tests reflect acute changes in metabolism, and are needed for immediate patient management and rapid results are required (<30 min). The concept of turn-round time is from the sample being taken to the requesting clinician assessing the significance of the result; so called 'vein to brain' time.

Many other tests are clinically useful if available within 3–4 h of receipt; others, of less immediate but possibly of as great clinical importance, greater complexity or greater cost, may require several days turn-round; they may be so rare, difficult or costly that they need to be sent to a specialist center.

The unique accession number given to a sample on receipt follows it through the analytical phase to the production of the final report. Machines with bar-code reading capability can read bar-coded laboratory accession numbers and link these with associated reports for these patients via computer interfacing. This allows the production of a cumulative report from which disease trends can be assessed. Bar-coded primary sample tubes (i.e., no aliquoting) can be handled on these analyzers.

Better integration of laboratory information management systems with hospital patient administration systems is resulting in tests being ordered at ward or primary care level with electronic result returns greatly improving the electronic patient record and minimizing delays. This is enhanced by positive patient identification with patients having bar-coded labels using palm computers, which enables production of requests and consideration of results at the bedside. This approach minimizes mixing of patients samples and enhances patient safety.

## Analytical Goals

As all analysts know, there is inherent imprecision in any analytical system. The question is at what point does the imprecision become acceptable for the purpose for which the analysis is going to be used. In clinical analysis this can be addressed by determining

what the biological analyte variability is in a population. It has been determined that analytical imprecision should be no greater than 25% of the population biological variation. The goal for bias is always zero, however, if the source and degree of interference are known this does not preclude the use of that analytical method. For example, recommendations on cholesterol screening advise a bias of zero and an imprecision of better than 3%. This enables significant changes to be detected. Using the Jaffe reaction to assay creatinine, a marker of renal function, imprecision is of the order of 5% and there is positive interference from ketones, which occur in diabetic coma and negative interference from bilirubin, the cause of the yellow color in jaundice.

Perhaps half of the methods in current use meet the current analytical goals. The clinical benefit that derives from meeting these goals has not been demonstrated to evidence-based medicine standards.

## Practical Aspects of Analysis

### Sample Handling

Clinical analysis is performed on a variety of matrices: whole blood (e.g. in hematology), serum, from clotted blood, or plasma from anticoagulated blood (both in clinical chemistry), urine, other fluids (e.g., amniotic fluid), feces, tissues, and occasionally on other matrices. Normally analytes are measured in serum, as it is easily accessible and is used to reflect target concentrations in tissue or receptors. Generally urine is examined to assess renal tract function and integrity.

Owing to the high workloads (often 2000 or more samples per day), samples are uniquely identified with a laboratory accession number. If serum or plasma is required, the blood sample is centrifuged (at ~3000 rpm) and the serum or plasma may be removed but primary tube sampling is now prevalent and a gel separator allows 'pouring off' of the supernatant if desired (see the section 'Large-capacity analyzers').

Sending samples to the correct path, aliquotting for different analytical workstations and tracking of samples is difficult and time-consuming. Given the volume of work in clinical laboratories and the potential significance of the results, these aspects are very important. The preanalytical requirements are now being automated. With bar-coded samples and host-query interfacing it is possible to correctly divide aliquot appropriate volumes and rack for analysis automatically. Following analysis automated sample handling enables X–Y–Z (column–row–rack)

storage and retrieval to be readily achieved, such systems range in price from £60 000 upward.

Traditional wet-chemical procedures required serum or plasma proteins to be removed prior to further analysis; this was achieved by precipitation, usually with acids such as trichloroacetic acid or metal ions, e.g., zinc sulfate. If organic acid extraction were to be used, this would also precipitate proteins. Such methods are scarcely used in routine practice. Automated procedures can readily be adapted to determine colorimetric endpoint or rates of reaction; the avoidance of protein interference is more difficult (see the section 'Large-capacity analyzers').

### Calibration

It is clearly recognized that analytes in aqueous solution do not perform in the same way as analytes in a biological matrix; it is therefore necessary to use, e.g., serum as diluent. Owing to the cost, and more recently health hazards, nonhuman, usually bovine, serum may be used. This can cause problems for some analytes, e.g., albumin.

Some analytes are difficult to standardize owing to the complexity of developing a primary standard, or analyte inhomogeneity, an International Standard is used to provide comparability. Such standards are based on the principle of transferability. A definitive method, e.g., isotope-dilution mass spectrometry (MS), is used to obtain the best possible estimate of the accurate concentration of the analyte. This value would be transferred to a reference method, which is usually a very carefully documented analytical procedure of known and impeccable performance, e.g., Abel-Kendal assay for cholesterol, and standards are compared in the procedure before being used in the filed.

### Quality Control

Internal, i.e., within department, quality control utilizing material of known concentration is used to assess the precision and bias of the assay. Inadequate analytical performance in internal schemes will result in rejection of the results from the analyzed samples. Performance criteria may simply be assessed as  $>2$  standard deviations from the mean or by more complex bias and imprecision estimates such as Westgard rules. Rejection of quality control may require analyses to be rejected, corrective action to be taken, and the analyses repeated.

External, i.e., outside-department, quality assurance schemes compare the accuracy of different methods and may derive targets from an all-laboratory trimmed mean (i.e., outliers discarded), on spiked values, or on a reference standard; usually

means and variance for method types are given. The consensual nature of such schemes validates the control material values and these can then be used by analytes, which correct poor method performance. The identities of the laboratories are unknown to all but the scheme organizers. In external schemes, in the event of difficulty there may be a communication followed by a visit from the panel of experts to help resolve a problem; in some countries continued poor performance will result in the laboratory losing its license.

### Units Used in Reporting

There is a diversity of units of concentration in use in analytical clinical biochemistry; however, clinical laboratories in Europe and elsewhere (except the United States) use the SI (System International) units. The base unit of volume is always the liter (written as/l), the concentration is expressed in moles or part thereof, e.g., micromole; numerical values should, ideally, be written between 1 and 999 per liter, e.g.,  $232 \text{ nmol l}^{-1}$ .

Archaic legal requirements, e.g., to report ethanol in milligram percent are sometimes used. To use molar units, the molecular weight of the species must be known as well as its degree of heterogeneity; for proteins, e.g., hemoglobin, the results are expressed as mass per liter, e.g.,  $\text{g l}^{-1}$  as there is high heterogeneity.

Worldwide agreement on the units to be used in analytical clinical biochemistry would greatly facilitate exchange of information and minimize unnecessary errors.

## Automation

### Large-Capacity Analyzers

Increasing workloads meant traditional manual wet-chemistry methods were too time-consuming and better diagnostics demanded better accuracy and precision. The first successful automation, in the early 1960s, was Skeggs continuous flow air-segmented systems in which a peristaltic pump utilizing tubing of different internal diameters proportionally delivered reagents, diluent, sample, and air for subsequent dialysis to remove protein and colorimetric or flame photometric analysis. Single analyte analyzers (Figure 1) were combined to produce the multichannel (multianalyte) analyzers. Analytical speeds of initially 20–60 samples per hour could be increased to 120 samples per hour for up to 24 different chemistries, but the inexorably increasing workloads exceeded the capabilities of this technology.

**Figure 1** Flow diagram of a typical single-channel, segmented flow Auto Analyser®.

**Figure 2** Flow diagram of a typical discrete analyser.

Discretionary analysis, as opposed to multianalyte panel screening developed from the realization that nonselective screening did not yield the expected health benefits. This approach was best addressed with discrete analyzers.

These modern discrete analyzers (Figure 2), typically utilize wet-chemistry with photometry of selective electrodes for the cations sodium and potassium. Dry-film technology using similar measurement principles are a significant minority of clinical analyzers. Each test is delivered as an individual slide, which minimizes infection risks. Either type allows different mixtures of tests within a defined menu to be done on different samples during the same analytical run (discretionary). The protein problem is circumvented by sample dilution and the use of surfactants.

Discrete analyzers can operate at up to 300 samples per hour, but may be dependent on the number

of tests requested per sample; speeds of 150 samples per hour for 16 tests or more are readily and commonly achievable. The other major advance was to move away from batch to random-access operation; this optimizes machine operations and uses bar-coding to enable random loading of the machine. Photometric detection is of either endpoint reactions or rate of reaction. Ion-selective electrodes are used to detect electrolytes. Many assays are based on enzymes specific for the substrate, with measurement of NADH/NADPH production or utilization or colorimetry of an end product. Users may be tied to the manufacturers' chemistries, but there is a trend to more 'open' systems where the analyst can use alternative chemistries. Combination of chemistry analyzers with immunoassay analyzers improves efficiency, these may be as an integrated analyzer or joined by a track system; they are further enhanced by linked preanalytical sample handling. Such

combinations are becoming increasingly popular despite the changes to building structures that they entail. Such analyzers can cost well over £200 000.

### Medium-Capacity Analyzers

Today such analyzers are discrete analyzers operating at high throughput on a wider menu of tests than their large cousins. They are usually suited to more sophisticated chemistries, such as those used in specific protein analysis or enzyme-mediated immunoassays for drug analysis.

### Specialized Analyzers

A number of specialized analyzers are found in clinical laboratories. They include machines to measure blood gases, serum and urine osmolality, and blood glucose.

### Point of Care Testing

Tests performed outside clinical laboratories are attracting increasing interest. Complex technology and chemistry are combined in easy-to-use machines; dry-film technology is the commonest technique used. The philosophy is that economically the immediacy of the result offsets the high consumables costs. For many analytes there is no need for such immediacy; however, patients can perform their own home glucose monitoring, GPs and others may offer cholesterol analysis as part of an assessment of cardiovascular disease, and intensive therapy units in hospitals invariably have blood gas machines to hand.

Clinical laboratories have a constructive approach to these developments and should offer training to operators and local quality control schemes to ensure that equipment is used correctly and is performing to specification. Problems in point of care testing include the use of inappropriate chemistries, operator-mediated analytical error, the use of inappropriate units of concentration; this results because the United States, unlike nearly every other country, does not use molar SI units for reporting clinical laboratory values (see the section 'Units used in reporting') and the failure to permanently record the results. These machines and their misuse have resulted in hazard warning notices from the Department of Health in the United Kingdom and the inclusion of such testing under the Clinical Laboratory Improvement Act 1988 in the United States. A significant issue is the lack of unequivocal integration of results in the electronic patient record.

## Other Techniques

Clinical laboratories also utilize fluorescence, cell culture techniques, and DNA analysis, depending on the demands made on them.

### Immunoassays

A significant proportion of many clinical laboratories' workload is dealt with by one or other form of immunoassay; drugs; proteins and hormones (steroid and protein). Radioisotopic assays (RIA) are now rarely used having been supplanted by safer non-isotopic automated analyzers. There has been rapid growth in the development of immunoassay analyzers with the ability to measure a wide range of hormones, tumor markers, and hematinics. These are high-capacity analyzers. Different antibody specificities and variation in calibrator material makes comparison of results between different machine types problematic. This is slowly being addressed. Combined general clinical chemistry analyzers with immunoassay analyzers are now available. Some suppliers provide 'track' systems enabling full automation of the combined sample reception and analytical process.

### Atomic Absorption Spectrometry

Determination of heavy metals and trace elements, e.g., lead, cadmium, copper, and zinc are best measured using atomic absorption. Electrothermal equipment has a wider application owing to its greater sensitivity. The workload, limited application of the tests, and the capital cost of equipment mean that spectrometers are located in larger laboratories. Inductively coupled plasma-mass spectrometry (ICP-MS) is used in some specialist centers, supplanting atomic absorption spectroscopy.

### UV-Visible Spectrophotometry

Spectrophotometry is the mainstay of the main chemical analyzers. However, stand-alone machines are occasionally used to measure colorimetric and endpoint assays. There has been a recent resurgence of interest in the use of visible spectrophotometry to detect bilirubin released following an intracranial bleed not detected by CT scan.

### Chromatography

Chromatography is used in a small proportion of routine clinical analysis. The sequential nature of sample introduction in column chromatography and the labor-intensive nature of thin-layer chromatography

means that chromatography is reserved for special assays where the ability to simultaneously determine metabolites and/or classes of compounds provides a distinct benefit e.g., amino acid analysis, anticonvulsant analysis.

Liquid chromatography (LC) is the most common of the chromatographic modes, as it has more general application in clinical laboratories than gas-liquid chromatography. Thin-layer chromatography is used for qualitative procedures, e.g., screening for drugs of abuse. Larger clinical laboratories will have a gas-liquid chromatograph and liquid chromatograph. The commonest use of LC is to measure hemoglobin A<sub>1c</sub> as a marker of diabetic control. Mass spectrometric detection linked to gas chromatography is used to confirm drugs of abuse by immunoassay screens. LC tandem MS have proven invaluable for screening for inborn errors of metabolism in pediatrics.

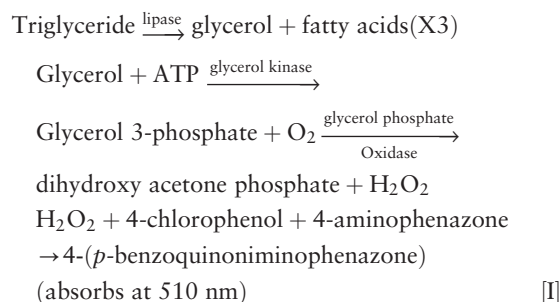

### Electrophoresis

Electrophoresis on cellulose acetate once widely used from separating serum proteins has been replaced by commercial high-resolution gel electrophoresis.

Isoelectric focusing for specific applications such as cerebrospinal fluid oligoclonal bands is of more specialist interest. Immunoelectrophoresis (i.e., electrophoresis followed by the application of specific antibodies) for typing monoclonal gammopathies (myelomas) is the procedure of choice. Capillary electrophoresis offers the opportunity to determine genotypes for homo or heterozygotes of, e.g., enzyme defects, following polymerase chain reaction.

### Enzymes

Enzymes are detected in serum as markers of damage to cells or induction of synthesis. Enzymes are also used as reagents; commonly the product is linked to a color reaction with, for example, 4-aminophenzone (see eqn [I]).

Alternatively, the enzyme reaction is NAD- or NADP-linked; the change from or to the reduced

form can then be monitored (see eqn [II]).

The use of immobilized enzymes minimizes costs, but most analyzers still use liquid reagents.

### Future Directions

In clinical laboratories sample handling, including analysis, is becoming much more automated, requiring lower skill levels; point of care testing will further increase. There will be a need for central clinical laboratories to participate in point of care testing to ensure that high standards of analysis are set and maintained. Perhaps more routine testing out of centralized laboratories into the community: a disseminated laboratory.

New techniques will be introduced, e.g., proton nuclear magnetic resonance (NMR) spectroscopy of biological fluids or perhaps combined NMR imaging with spectroscopy allowing *in situ* analysis.

With the sequencing of the human genome DNA analysis will make a significant contribution to determining the individuals susceptibility to disease. Currently DNA analyzers main contribution is to the identifications of infective agents, in assessing tumor susceptibility and in the diagnosis of inborn errors of metabolism. To harness these advances, different, probably more sophisticated samples will be required. The next challenge is proteomics: exciting times lie ahead for clinical analysis.

### Introduction

During pharmacokinetic and metabolism studies, as well as during routine therapeutic drug monitoring, the levels of the drug and its metabolites are commonly monitored in biological matrices (blood, plasma, serum, saliva, urine, bile, feces, cerebrospinal fluid, tissues, and *in vitro* biological samples). However, there are many analytical issues that must be addressed including (1) low concentrations of drugs in the matrices, (2) the complexity of biological materials, (3) small sample volumes, and (4) the choice of the analytical method to accurately quantify the drug in the matrix. Among the different analytical methods available, gas chromatography (GC), and high-performance liquid chromatography (HPLC) are among the most widely used. However, as the majority of drugs are nonvolatile, their analysis by GC requires that they be derivatized to render them amenable to gas-phase analyses. Thus, HPLC based on traditional detection methods, such as ultraviolet and fluorescence is widely used. Indeed, this method is particularly well adapted to the analysis of drugs and their more polar metabolites. In the past few years, the use of liquid chromatography coupled with mass spectrometry (LC-MS) or with tandem mass spectrometry (LC-MS/MS) has been growing in importance especially with the introduction of the electrospray interface.

The aim of this article is to present the different methods used in sample preparation for biopharmaceutical analysis. Their advantages, disadvantages, and the possibility of automation will be presented.

Before proceeding to discuss the relevance and methodology of sample pretreatment in bioanalysis, it is worth noting that in a few limited instances, it is possible to inject untreated body fluids directly onto the analytical HPLC column. This approach is not possible in GC. Direct injection is only feasible for samples (urine or bile, for example) containing high drug concentrations of the analyte(s) and very low protein concentrations. In this case, the matrix is simply diluted in deionized water before injection. This approach is difficult for serum or plasma samples due to the problem of protein precipitation on

the analytical column. However, columns have been specially designed for direct injection of serum or plasma. These columns totally exclude proteins while retaining smaller organic molecules.

In most instances, a biological sample containing a compound of interest requires some kind of sample pretreatment. Such procedures are principally carried out to isolate the drug from interfering matrix substances, but they also serve to liberate the drug from protein-binding sites and to concentrate the drug for more sensitive analysis. Indeed, removal of endogenous components is particularly important where these interferents become irreversibly adsorbed onto the packing material of the column, as is the case with lipids, or precipitated in the chromatographic system, as is the case with proteins.

### Elimination of Interfering Compounds

#### Ultrafiltration

Since it is not the total, but rather the free drug concentration that correlates with the concentration at the site of action, the free drug concentration is often considered as the best estimate of the pharmacologically active drug concentration. A protein-free solution may be obtained by filtration through a size-selective semipermeable membrane under pressure or by centrifugation in a membrane cone. The separation of free drugs is now simplified by the availability of ultrafiltration devices. Among the most widely used commercially available kits are Centrifree and MPS micropartition devices from Amicon (molecular weight cutoff 30 000 Da), 'Emit' free level filter system from Syva, and Molcut II from Millipore (molecular weight cutoff 10 000 Da). Ultrafiltration membranes are microporous in their structure; all molecules greater than the largest pore diameter are retained and all the other molecules, smaller than the smallest pore pass completely through the membrane. The hydrostatic pressure applied during the ultrafiltration process varies between 1 and 10 atm. However, there are some problems associated with ultrafiltration such as (1) adsorption of the drug onto the inert membrane, particularly if the drug is present at trace levels, (2) leakage of bound drug through membrane, (3) stability of the binding equilibrium during the separation process, and (4) a major factor limiting the speed and effectiveness of the process is the buildup of a layer of proteins on the upstream surface of the membrane.

**Table 1** Reagents used for protein precipitation

Principle	Reagent
Modification of the ionic strength	Saturated solution of ammonium sulfate
Insoluble salt precipitation	
Acidic precipitants	10–20% trichloroacetic acid (v/v) 10–20% perchloric acid (v/v) 5% metaphosphoric acid (v/v)
Basic precipitants	Zinc sulfate–sodium hydroxide Zinc sulfate–barium hydroxide Copper sulfate–potassium hydroxide
Modification of dielectric constant	Acetonitrile Methanol Ethanol Acetone

### Protein Precipitation

Protein precipitation can be obtained by modification of (1) the ionic strength, (2) the pH, or (3) the dielectric constant (Table 1).

Proteins are positively charged in strongly acidic solutions and negatively charged in strongly basic solutions, owing to their zwitterionic nature. Acidic or anionic precipitants form insoluble protein salts with the positively charged amino groups of proteins at low pH. Trichloroacetic and perchloric acids are widely used to separate compounds from tissue and blood samples. After centrifugation, an aliquot of the supernatant may be injected into the analytical column. To avoid damaging the column, the analyst must use a column specifically designed for operation at low pH or use a mobile phase containing a high molar concentration of buffer. Acidic protein precipitants are obviously unsuitable for compounds which are prone to acid hydrolysis. Proteins may also be precipitated by using cationic precipitants; these reagents form insoluble protein salts with the carboxylate groups of proteins. This method is unsuitable for compounds that have a tendency to form metal complexes. Cationic and acid protein precipitants may be used in conjunction with organic precipitants. If precipitation is effected by the addition of inorganic salts, the supernatant liquid will contain other constituents besides proteins, and frequently the drug peak can be accompanied and complicated by several other peaks which adversely affect assay precision. Where dilution of the sample is not of major importance, organic precipitants should be considered as they are less aggressive than the ionic precipitants.

With the addition of a water-miscible organic solvent to a biological sample such as serum or plasma, the solubility of proteins is lowered and they

**Table 2** Efficiency of protein removal from plasma according to the proportion of water/organic solvent

	Organic solvent/plasma (v/v)				
	0.2	0.6	0.8	1.0	2.0
Acetonitrile	13.4	45.8	88.1	97.2	99.7
Acetone	1.5	33.6	71.0	96.2	99.4
Methanol	17.6	32.2	49.3	73.4	98.7

From Blanchard J (1981) Evaluation of the relative efficacy of various techniques for deproteinizing plasma samples prior to HPLC analysis. *Journal of Chromatography Biomedical Applications* 226: 455–460.

precipitate out. The sample is centrifuged to produce a clear supernatant containing the compound of interest, and an aliquot is injected onto the column. It is important to use a protein precipitating solvent in which the analyte is highly soluble, otherwise it may adsorb onto, or co-precipitate with the protein. Diluting the plasma (or serum) up to threefold with the organic solvent will effect removal of 99% of the proteins (Table 2), but effectively decreases sensitivity of the method. This drawback can be counteracted to some extent by increasing the volume of injection, though this can adversely affect chromatographic efficiency and peakshape. Alternatively, the supernatant may be evaporated, but this measure also concentrates any remaining interfering compounds. Alternatively a water-immiscible organic solvent, such as dichloromethane, may be added to the mixture. In this case, the lower layer is a mixture of dichloromethane–acetonitrile (or methanol) and the supernatant is the aqueous phase. These two phases can be separated using phase separators such as silicone-treated filter paper Whatman 1 PS.

### Demixing (Salting-Out) Method

This method is particularly well adapted to drug-level monitoring. It has been used in the determination of antifungal agents and more recently it was employed in the quantitation of antiproteases in plasma. Its principle is as follows: a water-miscible organic solvent is added to the biological sample, followed by an excess of salt (sodium carbonate, potassium chloride, or sodium chloride). Polar water-miscible solvents are forced to form a separate layer using this salting out technique, resulting in four different phases (Figure 1). The analyte is generally present in the organic layer, which may be injected directly onto the column. The advantage of this technique includes its simplicity and rapidity, and dilution of the analyte may be circumvented by

**Figure 1** Demixing (salting-out) method.

evaporating the organic solvent, though this step considerably lengthens the procedure.

## Liquid-Liquid Extraction

### Classic Liquid-Liquid Extraction

Liquid-liquid extraction is a very widely used method for the preparation of biological samples for subsequent analysis. Convenience and ease of use have contributed to the large popularity of this technique. In addition, liquid-liquid extraction permits concentration of the analyte.

This technique is based on the extraction of a drug depending on its partition between an aqueous and an immiscible organic phase. The partition coefficient ( $K_i$ ) of a drug  $i$  is given by

$$K_i = \frac{[C_i]_{\text{org}}}{[C_i]_{\text{aq}}}$$

where  $[C]_{\text{org}}$  and  $[C]_{\text{aq}}$  are the concentrations of drug in the organic and aqueous phases, respectively. Hence, the degree of solvent extraction is dependent on  $K_i$ , which in turn is dependent on the type of organic solvent as well as the pH and ionic strength of the solution. It is well known that repeated extractions (two or more) with small portions of solvent can recover more analyte than a single batch extraction, but for practical purposes, a biological sample is extracted no more than twice in most applications.

The solvent is selected to provide maximum extraction efficiency and minimum contaminants.

Polarity is usually the most important factor in the choice of the extraction solvent, and generally as this increases, the range of compounds extracted also increases. Hence, the solvent should be selected with minimum polarity consistent with high recovery of the drug. Drugs of high polarity are difficult to extract and require polar and consequently nonselective solvents. In some cases, to avoid losses by adsorption onto glass material, to increase the reproducibility of extraction, and to allow the extraction of more polar metabolites simultaneously with the parent drug, it is possible to select a mixture of solvents (1–5% of alcohol added to nonpolar organic solvents). For example, a mixture of methylene chloride-isopropyl alcohol (4:1, v/v) is used to extract a zwitterion, pefloxacin, from plasma and tissues.

Only the unionized form of a drug is extracted into the organic solvent. Therefore acidic drugs, which are unionized under acidic conditions are extracted from acidified matrices into organic solvents; basic drugs are likewise extracted from basified matrices. The optimal pH for acidic species is 1–2 pH units below their  $pK_a$  values, and for basic species it is 1–2 pH units above their  $pK_a$  values. Extraction can be difficult for compounds which are soluble in water at all pH values, for example water-soluble amphoteric and neutral drugs. In some cases, the addition of buffer salts to the aqueous solution increases its ionic strength and hence its polarity. This tends to decrease the affinity of polar compounds for the aqueous phase, and thus shifts the partition equilibrium in favor of extraction.

In order to increase the purity of extracts, interfering compounds may be preextracted into an organic phase which is then discarded. For example, urine contains many endogenous compounds, and a preliminary extraction from acidic urine improves the purity of a subsequent basic extract. Another useful method is back-extraction. By adjusting the pH of a new aqueous phase to that which will reionize the analyte, it can be back-extracted from the organic phase into the new aqueous layer. For back-extraction of basic drugs into an acidic phase, sulfuric and phosphoric acids are preferred to hydrochloric acid because many hydrochlorides are soluble in organic solvents. Back-extraction is more or less mandatory in GC since interfering substances in the initial extract tend to contaminate GC detectors, particularly nitrogen-phosphorus and electron capture detectors. This approach, when used prior to HPLC analysis, greatly improves the extraction selectivity, though overall recovery of the drug can be reduced and it adds considerably to analysis time.

### Ion-Pair Extraction

A useful method for dealing with a highly polar ionic drug is to convert it into a neutral ion-pair (IP) complex by the addition of an excess of suitable ions of opposite charge, followed by extraction of the complex into an organic solvent.

The extraction constant ( $K_{\text{ex}}$ ) is given by

$$K_{\text{ex}} = \frac{|\text{AQ}|_{\text{org}}}{|\text{A}^-|_{\text{aq}} \cdot |\text{Q}^+|_{\text{aq}}}$$

Table 3 lists common ion-pairing (IP) reagents. Formation of the complex depends on factors such as the pH of the aqueous phase, the type of organic solvent, and the nature and concentration of the counter ion. The IP extraction technique is useful for a variety of ionizable compounds which are difficult to extract in the unchanged form such as penicillins, amino acids, and conjugated metabolites. This method allows extraction of quaternary ammonium compounds such as tubocurarine which are ionized at all pH values.

**Table 3** Common ion-pairing reagents

<i>For basic analytes (most as sodium salt)</i>	<i>For acidic analytes</i>
Propanesulfonic acid	Triethylamine
Butanesulfonic acid	Tetramethylammonium bromide (or hydrogen sulfate)
1-Pentanesulfonic acid	Tetraethylammonium bromide (or hydrogen sulfate)
1-Hexanesulfonic acid	Tetrapropylammonium bromide (or hydrogen sulfate)
1-Octanesulfonic acid	Tetrabutylammonium bromide (or phosphate, iodide)
1-Nonanesulfonic acid	Tetrapentylammonium bromide
1-Decanesulfonic acid	Tetrahexylammonium bromide (or hydrogen sulfate)
1-Dodecanesulfonic acid	Tetraheptylammonium bromide
	Tetraoctylammonium bromide
Dodecylsulfate, sodium salt	Hexadecyltrimethyl ammonium hydroxide (or bromide, or hydrogen sulfate)
Diocylsulfosuccinate, sodium salt	Decamethylenebis (trimethylammonium bromide)
Trifluoroacetic acid	
Pentafluoropropionic acid	
Heptafluorobutyric acid	
Bis-2-ethylhexylphosphate	

In some cases in HPLC, the IP agent can be added to the mobile phase to reduce the retention times of the solutes and to obtain an acceptable asymmetry coefficient. For example, the retention times of enoxacin and its 4-oxo metabolite and of pefloxacin decrease as the concentration of tetrabutylammonium hydroxide in the mobile phase increases and the peak sharpens as a consequence of this decrease in retention time.

### Solvent Extraction Following Derivatization

Derivatization is commonly used to improve analyte detectability, although in some cases, derivatization is necessary to release analytes from their binding sites. For example, the antineoplastic agent cisplatin is chelated with diethyldithiocarbamate before HPLC–UV analysis.

### Problems with Liquid-Liquid Extraction

Solvent extraction is relatively time-consuming. It often requires the removal of solvents by evaporation. This lengthy step may also lead to decomposition of unstable compounds, particularly when heating is required. Losses can also occur at the redissolution stage. Another problem is the risk of adsorption of analytes onto glassware which can occur at the stage of extraction or solvent evaporation. Adsorption is much more noticeable when a drug is present at low concentrations. This problem may be partially overcome by (1) silanization of glassware, (2) the inclusion of 1–2% ethanol, isopropanol, or isoamyl alcohol into the extracting solvent, or (3) the use of polypropylene test tubes. These measures are, however, not always effective, and others may have to be devised.

### Offline Solid-Phase Extraction

Solid-phase extraction (SPE) has been available to analytical chemists for more than two decades. SPE often results in lower detection limits compared to other methods of sample preparation.

The principle of SPE is selective retention of the analytes on the sorbent by nonpolar, polar, and ionic interactions, and affinity and partition between the analytes, the sorbent, and/or the solvent.

Several SPE formats are commercially available and they may be divided in two broad categories. The first category includes hydrophilic packing materials such as inert particles of diatomaceous earth (kieselguhr). The sample and the water it contains are absorbed over a large surface area forming a thin aqueous film over the surface of each particle. A small volume of a water-immiscible organic solvent

such as dichloromethane is then passed through the column extracting the drug from the aqueous film of sample. Water and endogenous materials, such as pigments or other polar compounds are retained in the absorbed phase. The second category is based on the principles of chromatography. A six-step SPE protocol is the most common approach.

### Principle of the Six-Step Extraction Procedure

In each of the steps, conditions must be optimized for interaction between the analyte(s), matrix, and sorbent. These conditions include pH, ionic strength, solvent strength, solvent volume, and flow rates.

**Step 1: sample pretreatment** This step involves preparing the sample both physically and chemically for SPE extraction so that optimal conditions exist for analyte retention. The type of sample pretreatment is dependent on the analyte (particularly its stability), the type of matrix, the type of sorbent, and the nature of the analytes/sorbent interactions.

For aqueous samples containing analytes that are to be retained primarily by hydrophobic interactions, pH adjustment may be required to ensure that the surface and analyte (if ionizable) are not charged. It may be necessary to add a wetting agent (e.g., 1–2% methanol) to maintain an active sorbent surface. Where the primary interaction for analyte retention is ion exchange, the pH should be controlled to ensure complete ionization of the analyte and surface of the sorbent. The selectivity of the buffer cation (for cation exchange) or anion (for anion exchange) should be taken into account. Buffers that contain ions of lower affinity for the sorbent than the analyte itself facilitate analyte retention. The selectivity of some common cations is as follows (ions on the right will displace those on the left):

Selectivity of some common anions (ions on the right will displace those on the left):

Dilution of viscous samples may be necessary to reduce sample viscosity and to ensure a free-flowing sample.

**Step 2: SPE column conditioning** This step prepares SPE column for the extraction process by enabling the bonded phase to interact with the sample matrix. For aqueous samples the sorbent is wetted with an organic solvent such as methanol. It is important

when using nonpolar sorbents so that a residual amount of the solvent remains in order to keep the sorbent ‘wetted’. For nonaqueous samples, the sorbent is wetted with the matrix solvent. The volume of conditioning solvent is  $2 \times 1.0$  ml of solvent per 100 mg sorbent.

**Step 3: SPE column equilibration** This step removes excess conditioning solvent. To maximize analyte retention, the sorbent is treated with a ‘matrix-like’ solvent. For aqueous samples, the solvent should be similar to the sample matrix in terms of pH and ionic strength (if the retention mechanism is ion exchange, an ionic strength  $< 0.05$  M should be used). This step is not required for nonaqueous samples.

Proper conditioning is important for conventional reverse-phase supports, which require a ‘wetting’ step with a polar organic solvent followed by sorbent equilibration prior to sample application (steps 2 and 3) to ensure reproducible results. However, SPE columns that do not require preconditioning are now available. Such sorbents have been developed in response to the changing pace of drug discovery – high throughput screening LC–MS, tougher legislation on solvent use, and safety requirements.

**Step 4: sample loading** During this step, it is essential that the correct loading flow rate is used. In method development, it is important to start with a low flow rate to ensure that optimum recoveries are obtained. A good starting point is  $1 \text{ ml min}^{-1}$  for a 1 ml cartridge,  $3 \text{ ml min}^{-1}$  for a 3 ml cartridge and  $7 \text{ ml min}^{-1}$  for a 6 ml cartridge. Once the method chemistry has been established, the flow rate can be increased until some sample breakthrough (i.e., a drop in recovery) is observed. A flow rate which is slightly lower than the upper limit should be used.

**Step 5: interference elution step** This step selectively removes undesired compounds from the sorbent without eluting the analytes. Generally, the solvent used (1–2 ml for 100 mg of sorbent) is miscible with the sample matrix. For aqueous samples, the ionic strength and pH should be maintained to prevent analyte losses. The flow rate should be adjusted so that the solvent is in contact with the sorbent for 1–2 min. If the elution solvent is water-immiscible, drying of the column is required.

**Step 6: analyte elution** The solvent used must be one in which the analytes are soluble and that overcomes both primary and secondary sorption interactions. Small volumes of elution solvents should be used ( $250 \mu\text{l}$  per 100 mg of sorbent). The use of two small aliquots of solvent with a 1–4 min soak step

**Table 4** Properties and applications of the most widely used sorbents

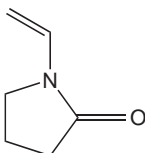

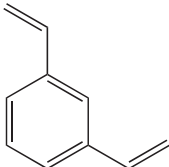

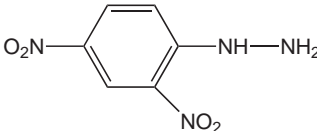

Sorbents	Retention mechanism	Applications
<b>Silica-based nonpolar</b>		
Monofunctional silane: C <sub>18</sub> , C <sub>8</sub> reversed-phase R <sub>1</sub> = (CH <sub>2</sub> ) <sub>17</sub> CH <sub>3</sub> , (CH <sub>2</sub> ) <sub>7</sub> CH <sub>3</sub> ; R <sub>2</sub> and R <sub>3</sub> = CH <sub>3</sub> ; R <sub>4</sub> = H (NC)*	Nonpolar, polar, cation exchange	Aqueous medium Wide polarity range *pH range, 3–7.5
Trifunctional silane: C <sub>18</sub> reversed-phase R <sub>1</sub> = (CH <sub>2</sub> ) <sub>17</sub> CH <sub>3</sub> ; R <sub>4</sub> = H (NC) R <sub>1</sub> = (CH <sub>2</sub> ) <sub>17</sub> CH <sub>3</sub> ; R <sub>4</sub> = Si(CH <sub>3</sub> ) <sub>3</sub> (EC)*	Nonpolar, polar, cation exchange Nonpolar	Aqueous medium Wide polarity range *pH range, 3–7.5
Trifunctional silane: C <sub>8</sub> ; C <sub>6</sub> ; C <sub>4</sub> ; C <sub>2</sub> reversed-phase R <sub>1</sub> = (CH <sub>2</sub> ) <sub>7</sub> CH <sub>3</sub> , (CH <sub>2</sub> ) <sub>5</sub> CH <sub>3</sub> , (CH <sub>2</sub> ) <sub>3</sub> CH <sub>3</sub> , CH <sub>2</sub> CH <sub>3</sub> ; R <sub>4</sub> = H (NC) R <sub>1</sub> = (CH <sub>2</sub> ) <sub>7</sub> CH <sub>3</sub> , CH <sub>2</sub> CH <sub>3</sub> ; R <sub>4</sub> = Si(CH <sub>3</sub> ) <sub>3</sub> (EC)	Nonpolar, polar, cation exchange Nonpolar	Aqueous medium; wide polarity range; less retentive than C <sub>18</sub> ; retention properties, C <sub>8</sub> > C <sub>6</sub> > C <sub>4</sub> > C <sub>2</sub> if retention based on nonpolar interactions alone
Trifunctional silane: cyanopropyl R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> CN; R <sub>4</sub> = H (NC) R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> CN; R <sub>4</sub> = Si(CH <sub>3</sub> ) <sub>3</sub> (EC)	Polar if nonpolar matrix Nonpolar, cation exchange (NC) if aqueous medium	Can be used as a less polar alternative to silica in normal-phase applications or as less hydrophobic alternative to C <sub>18</sub> or C <sub>8</sub> in reversed-phase applications
Trifunctional silane: phenyl		
R <sub>1</sub> =  ; R <sub>4</sub> = H (NC)	Nonpolar, polar, cation exchange	Aqueous medium; wide polarity range; less retentive than C <sub>18</sub> ; different selectivity than C <sub>8</sub> and C <sub>18</sub> for aromatic compounds
R <sub>1</sub> =  ; R <sub>4</sub> = Si(CH <sub>3</sub> ) <sub>3</sub> (EC)	Nonpolar	
Trifunctional silane: cyclohexyl (EC)		
R <sub>1</sub> =  ; R <sub>4</sub> = Si(CH <sub>3</sub> ) <sub>3</sub>	Nonpolar	Aqueous medium; wide polarity range; less retentive than C <sub>18</sub> ; different selectivity from C <sub>8</sub> and C <sub>18</sub> for phenolic compounds
<b>Silica-based polar</b>		
Trifunctional silane: aminopropyl R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> NH <sub>2</sub> ; R <sub>4</sub> = H (NC)	Polar bonded phase with basic character if nonpolar matrix Anion exchange if aqueous medium	Can be used as a polar sorbent, like silica, with different selectivity for acidic/basic analytes or as a weak anion exchanger in aqueous medium
Trifunctional silane: diol R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> OCH <sub>2</sub> CH(OH)CH <sub>2</sub> OH; R <sub>4</sub> = H (NC)	Polar bonded phase with neutral character if nonpolar matrix Nonpolar, semipolar if aqueous medium	Can be used as an alternative to silica in normal-phase applications where the acidic character of silica is undesirable or as very weakly interacting phase in aqueous applications

Table 4 Continued

Sorbents	Retention mechanism	Applications
Other polar		
Silica	Polar sorbent The binding mechanism can be hydrogen bonding or dipole–dipole interaction Silanol groups are ionizable and unbounded silica can be used as a weak cation exchanger	To adsorb analytes from nonpolar solvents
Alumina	Available in acidic, basic, and neutral High activity grades	Similar to silica
Florisil <sup>®</sup> (magnesia–silica gel)	Polar highly active, weak-basis sorbent for adsorption	Adsorption of low to moderate polarity compounds from non-aqueous solutions
Silica-based anion-exchanges		
R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> NH <sub>2</sub> , (CH <sub>2</sub> ) <sub>3</sub> NH(CH <sub>2</sub> ) <sub>2</sub> NH <sub>2</sub> ; R <sub>4</sub> = H	Hydrophilic character Weak anion-exchangers (pK <sub>a</sub> = 9.8, 10.1 and 10.9) at pH ≤ 7.8, 8.1	Extraction of anionic analytes in aqueous and nonaqueous solutions
R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> N <sup>+</sup> (CH <sub>3</sub> ) <sub>3</sub> Cl <sup>−</sup> , (CH <sub>2</sub> ) <sub>3</sub> N <sup>+</sup> (CH <sub>3</sub> ) <sub>3</sub> CH <sub>3</sub> COO <sup>−</sup> ; R <sub>4</sub> = H	Strong anion-exchangers	
Silica-based cation-exchanges		
R <sub>1</sub> = (CH <sub>2</sub> ) <sub>3</sub> COOH	Hydrophilic character Weak cation-exchanger, (pK <sub>a</sub> = 4.8) positive charge at pH ≥ 6.8	Extraction of cationic analytes in aqueous and nonaqueous solutions
R <sub>1</sub> = benzene sulfonic acid, (CH <sub>2</sub> ) <sub>3</sub> SO <sub>3</sub> <sup>−</sup> H <sup>+</sup> , ethylbenzene sulfonic acid R <sub>4</sub> = H	Strong cation-exchangers	
Others		
Poly(divinylbenzene–vinylpyrrolidone) resin	Hydrophobic character	An alternative to octadecyl-bonded silica for analytes that weakly adsorb to silica-based reversed-phase sorbents
Hydroxylated polystyrene–divinylbenzene co-polymer	Hyper cross-linked sorbent The sorbent does not need to be conditioned before use	Extraction of polar compounds; high sample loading flow rates can be used
Polystyrene–divinylbenzene co-polymer	Nonselective polymeric phase; Highly cross-linked sorbent	Extraction of polar compounds that are not adequately retained on C <sub>18</sub> or C <sub>8</sub> sorbents
Hydrophilic–lipophilic balance reversed-phase sorbent: co-polymer of	Water-wettable sorbent	Widely used in forensic analysis High capacity and retention of a wide variety of analytes Column use pH 1–14

between elution volumes is often more efficient than one large aliquot. Flow control is important to ensure reproducibility. For analytes that are retained by ion exchange, high ionic strength ( $>0.1 \text{ M}$ ) buffers

can be used for elution. For doubly charged analytes, buffers of  $>0.2 \text{ M}$  should be used. An organic component in the elution solvent may be necessary to overcome secondary hydrophobic interactions. Thus,

the elution of an ionic compound may be obtained by using a counter ion of the same charge as the analyte but which has a higher affinity for the sorbent. Alternatively, the pH of the solvent may be adjusted to 1 or 2 pH units above or below its  $pK_a$  (depending on whether the analyte is acidic or basic) in order to suppress its ionization, thus lowering its affinity for the ion-exchange sorbent.

### SPE Extraction Columns

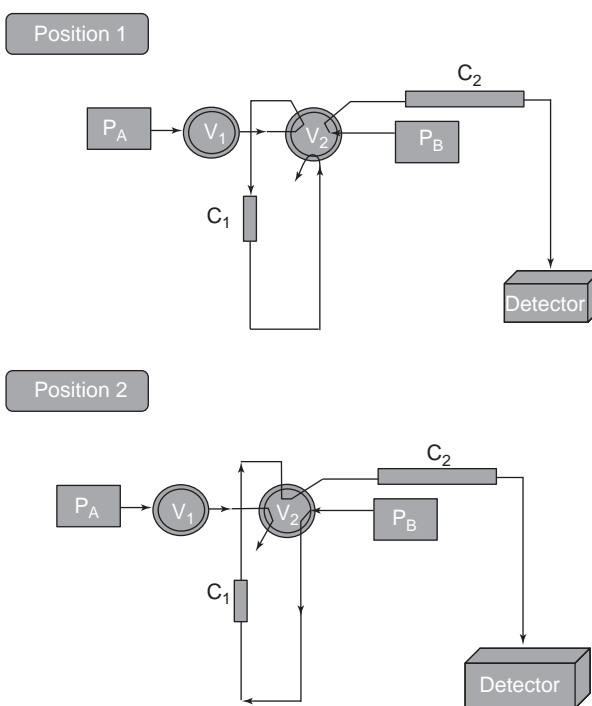

The most widely used sorbents with their characteristics are presented in **Table 4**. Mixed-mode columns containing mixtures of nonpolar ( $C_8$ ,  $C_{18}$ ,  $C_4$ , etc.) and strong anion or/and strong cation exchange functional groups are available for applications for both acidic and basic compounds. These columns are designed to capitalize on multiple interactions of the analyte or different types of interactions from more than one type of analyte. Mixed-mode columns allow the development of more robust procedures, which are less dependent on the matrix, making cleaner extracts possible.

IP SPE extraction is an additional method to the arsenal of techniques available to the analytical chemist. Cartridges containing  $C_{18}$ , phenyl, cyclohexyl, and polymeric media have been used in IP SPE. They are activated according to the manufacturer's recommendations followed by a solution of the IP reagent. IP reagent concentrations used range from 0.005 to 0.2 M. The same IP reagent is added to the samples before their application onto the conditioned cartridges. The cartridges may be washed with the aqueous IP reagent before elution with a stronger solvent, which may or may not contain the same IP reagent. Combining IP SPE with other SPE modes can yield substantial sample cleanup. One disadvantage of IP SPE is that occasionally there are problems with lot-to-lot differences of IP reagents that lead to variable recovery rates. IP SPE may also complicate and lengthen the method development process.

Recently, the use of 96-well SPE formats for extractions, automated using a robotic liquid-handling system, allows high throughput sample preparation.

### Online Solid-Phase Extraction

The typical scheme for an online sample cleanup procedure incorporating two pumps and a six-port switching valve is shown in **Figure 2**. Pump B is used to deliver the mobile phase and pump A is used to deliver the wash solvent, which is usually water or buffer, though a small percentage of organic solvent is sometimes added. In position 1, the wash solution

**Figure 2** Instrument arrangement for online solid-phase extraction with column switching.  $P_A$  and  $P_B$ , pumps;  $C_1$ , extraction column for the online SPE;  $C_2$ , analytical column;  $V_1$  and  $V_2$ , injection and switching valves; position 1, switching valve is positioned for online SPE cleanup and preconcentration; position 2, switching valve is positioned to transport sample to the analytical column.

is passed by pump A via the injector and the extraction column. Meanwhile, the mobile phase is pumped by pump B via the valve onto the analytical column, which is thus maintained in a state of constant equilibration. The sample was then loaded onto the extraction column, where cleanup and preconcentration take place. The polar matrix components are eluted to waste and the compounds of interest are selectively enriched on top of judiciously chosen sorbent. After a predetermined wash period, the valve is switched to position 2, the precolumn was then connected to the analytical column preferably in a back-flush configuration, where analytes were swept onto the analytical column by the HPLC mobile phase. The precolumn remains in line with the analytical column for predetermined period, and while the analytes are separated on the analytical column, the extraction column is re-equilibrated with the wash solution.

The column switching technique is particularly well adapted to biological fluids with low protein concentrations (for example, urine). For plasma samples, dilution or deproteinization may be required prior to injection into the extraction precolumn. It

should be noted that online SPE sorbents exist, known as 'internal surface reversed phase' that permit direct injection of protein-containing biological samples without prior cleanup.

## Electrolytes in Physiological Samples

**W R Külpmann**, Medizinische Hochschule Hannover, Klinische Chemie, Hannover, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

In clinical chemistry, the term 'electrolytes' is confined to anions and cations, which are present in high concentrations in comparison to trace elements, such as iron, copper, or zinc. Thus, electrolytes comprise sodium, potassium, calcium, magnesium, chloride, phosphate, and hydrogen carbonate (bicarbonate). Electrolytes are determined frequently in patient care, because the clinical symptoms of electrolyte disturbances are often, at least at an early stage, not very evident. In addition, the clinical symptoms are frequently not clearly associated with electrolyte disturbances, but are ambiguous and may be caused by other diseases. The concentration of the electrolytes in serum is held constant biologically within narrow limits. During infusion therapy, rapid changes of electrolyte concentration may occur and need thorough

and rapid monitoring. Fast determinations of most electrolytes are now possible by the use of ion-selective electrodes (ISEs), which give results within minutes for blood; hence, there is no loss of time due to centrifugation to obtain plasma and no delay for clotting to obtain serum. Reliability of the results is as essential as speed. Reliability is warranted by concomitant procedures of quality assessment and plausibility control, which, however, can only be used to a very limited and inadequate extent to monitor appropriate preanalytical handling (sampling, transport, storage).

## Sodium

### Methods and Techniques

Sodium is determined in physiological samples using flame atomic emission spectrometry (FAES), UV-visible spectrophotometry, or potentiometry. All the methods can be used for serum (for convenience and brevity, 'serum' here includes plasma obtained from heparinized blood) or urine, whereas blood can only

should be noted that online SPE sorbents exist, known as 'internal surface reversed phase' that permit direct injection of protein-containing biological samples without prior cleanup.

Reliability is warranted by concomitant procedures of quality assessment and plausibility control, which, however, can only be used to a very limited and inadequate extent to monitor appropriate preanalytical handling (sampling, transport, storage).

## Sodium

### Methods and Techniques

Sodium is determined in physiological samples using flame atomic emission spectrometry (FAES), UV-visible spectrophotometry, or potentiometry. All the methods can be used for serum (for convenience and brevity, 'serum' here includes plasma obtained from heparinized blood) or urine, whereas blood can only

be analyzed for its sodium activity in the extracellular water phase by potentiometry.

**Flame atomic emission spectrometry** Basic information on FAES is presented elsewhere in this encyclopedia. Sodium measurements are performed at 590 nm with the use of a propane flame (1925°C). Physiological samples for sodium determination are highly diluted before measurement. The diluent and the calibrator solution contain the same concentration of lithium ions so as to balance flame instability by a concomitant measurement of lithium in the reference beam (the so-called lithium guideline). At the same time, lithium ions inhibit the ionization of sodium atoms. This procedure cannot be used in the case of therapy with lithium salts. That is why some authors prefer the concomitant measurement of caesium to that of lithium. Dilution adjusts the viscosity of the sample to that of the calibrator solution to produce identical aspiration rate and drop size on nebulization. As other electrolytes interfere with sodium measurement, their concentration in the calibrator solution must be similar to their concentration in the sample. For the measurement of sodium in urine, calibrator solutions different from those for serum measurement are needed as the electrolyte concentrations in urine samples are quite different from those in serum and their relations are very variable. As the concentration of the electrolytes in serum is rather constant, calibrator solutions for serum measurements can fulfill their function better than those for urine; in other words, urine determinations are usually less accurate. FAES proved to be sufficiently reliable to be used as the basic principle of the sodium reference measurement procedure. In routine use, however, FAES is less accurate. Its application is given up by most clinical laboratories in favor of potentiometric measurements

**UV-visible spectrophotometry** With the advent of FAES, the determination of sodium with magnesium uranylacetate became obsolete, as this method was insufficiently reliable for the determination of physiological samples.

In 1988 however, new methods were described for the measurement of sodium in physiological samples by UV-visible spectrophotometry.

1. *Enzymatic determination.* The activity of  $\beta$ -galactosidase is specifically dependent on the sodium concentration, and is determined according to

It is measured by following the absorption at 405 nm. As a linear relationship is found only at low sodium concentrations, a defined proportion of sodium ions is bound to a kryptand before the enzymatic reaction. The method is applicable to serum and urine.

2. *Kryptahemispherand determination.* The reagent consists of (1) an ionophore, with a cavity tailor-made for sodium ions, and (2) a chromophore, bound to the ionophore, with a characteristic absorption spectrum at a certain pH adjusted by buffer. On binding of sodium, the absorption spectrum is shifted proportionally. The method is interfered with by lipids and bilirubin.

FAES and ISEs need additional equipment, and FAES is hazardous (because of the use of propane). In contrast, sodium measurements by UV-visible spectrophotometry can be performed on an instrument that is always available in a clinical laboratory.

**Potentiometry** For sodium determinations by potentiometry, a glass electrode is usually used, but ion-carrier or ion-exchange membranes are also feasible for the ISE. A silver/silver chloride or a calomel electrode is used as the reference electrode.

According to the Nernst equation, the potential of the ISE is proportional to ion activity:

$$E = E_0 + (RT) (zF)^{-1} \ln \gamma c \quad [2]$$

where  $E$  is the ion-selective membrane potential measured,  $E_0$  a constant potential,  $R$  the gas constant,  $T$  the temperature (K),  $z$  the charge of the ion measured,  $F$  Faraday's constant,  $\gamma$  the molal activity coefficient, and  $c$  the concentration.

*Undiluted samples:* The activity coefficient of sodium in serum is nearly constant (0.747), as the ion concentrations do not vary much in this system. Sodium ions bound to hydrogen carbonate, protein, etc., escape measurement by ISEs and are not recorded. On the other hand, the measurement is independent of the protein and lipid concentration, i.e., of the variable size of the compartment of macromolecules, that does not contain electrolytes (Figure 1). The relationship between concentration and activity is given by

$$C_{\text{Na}} = (\tilde{m}_{\text{Na}} \gamma^{-1} + m_{\text{NaHCO}_3} + m_{\text{Na Prot}} + m_{\text{NaX}}) \rho_{\text{H}_2\text{O}} \quad [3]$$

where  $C_{\text{Na}}$  is the sodium concentration,  $\tilde{m}_{\text{Na}}$  the active molality of sodium,  $\gamma$  the molal activity coefficient,  $m_{\text{NaHCO}_3}$  the molal concentration of sodium bound to hydrogen carbonate (bicarbonate),  $m_{\text{Na Prot}}$  the molal concentration of sodium bound to

**Figure 1** Fractions of sodium in serum. (Modified from Maas AHJ, Siggaard-Andersen O, Weisberg HF, and Zijlstra WG (1985) Ion-selective electrodes for sodium and potassium: a new problem of what is measured and what should be reported. *Clinical Chemistry* 31: 482–485.)

protein,  $m_{\text{NaX}}$  the molal concentration of sodium bound to other anions, and  $\rho_{\text{H}_2\text{O}}$  the mass concentration of water in serum.

Usually measurements by ISEs are reported as concentrations, assuming identical activity coefficients for the sample and the corresponding calibrator. The values will differ from concentration measurements (e.g., by FAES), depending on the protein and lipid concentration (which is expressed by the water mass concentration  $\rho_{\text{H}_2\text{O}}$ ). In sera of 'normal' water concentration, the differences between ISE measurements and concentration measurements are less than expected from theory (+2.5% instead of 7%) because of factors such as sodium binding (see eqn [3]) and residual junction potential. Values obtained from ISE measurements in undiluted samples must be reported separately, as they reflect the chemical potential of the component in the system, i.e., its activity and not its amount of substance concentration.

**Diluted samples:** In highly diluted samples, the activity coefficients are identical for the calibration solution and the analytical portion of the sample. The influence of water concentration and sodium binding is negligible. Accordingly, the concentration of sodium in the sample can be calculated from the concentration of the calibration solution. Thus, measurements by ISEs in diluted samples give comparable estimates of the amount of sodium in the

**Table 1** Reference intervals ( $\text{mmol l}^{-1}$ ) for electrolytes in serum (adults)

Calcium, total	2.15–2.55
Calcium, free ('ionized') (pH 7.4)	1.17–1.29
Chloride, total	98–106
Hydrogen carbonate (standard)	21–26
Magnesium, total	0.75–1.10
Phosphate (inorganic), total	0.87–1.45
Potassium, total	3.5–5.1
Sodium, total	135–145

The intervals are not method dependent, but are only valid for normal water concentration of the serum.

system, and accurate results of sodium concentration can be expected.

**Solid-phase chemistry** Potentiometry is also used for the determination of sodium concentration in solid-phase chemistry (Vitros, Ortho). The results usually compare well with measurements by FAES or ISEs in diluted samples, but differ in the case of paraproteinemia.

**Analytical reliability** A (between-day) coefficient of variation below 1.5% should be achieved in routine laboratory work with a bias of less than 2% from the target value to meet clinical requirements. All the methods are adequately sensitive and specific for physiological samples; however, some ISEs are less robust and more susceptible to interference than FAES.

### Significance and Interpretation of Results

Owing to the relatively small reference interval of sodium in serum (Table 1), a change in the water concentration has a large influence on the interpretation of sodium concentration. Sodium concentration decreases proportionally to the increase in protein and/or lipid concentration ('pseudohyponatremia'). Sodium concentration increases proportionally to the decrease in proteins. Therefore, before interpreting the results for sodium concentration in serum, one must be sure that the water concentration of the sample is not grossly aberrant from normal. Otherwise, the concentration has to be readjusted to be comparable to the reference interval. However, if measurement is performed by ISEs in the undiluted sample, the result can be interpreted without respect to water concentration. It reflects the sodium activity in the water phase, which is a more meaningful quantity in biological systems than concentration. The amount of sodium ions in the body is adjusted by the renin–angiotensin–aldosterone system, which influences the tubular reabsorption of sodium.

**Table 2** Disorders of sodium balance

1	Hyponatremia combined with hypotonic dehydration
1.1	Cause: Sodium loss exceeds water loss
	Examples: Polyuric renal disease
	Disturbance of tubular sodium reabsorption (e.g., interstitial nephritis)
	Adrenal cortical hypofunction
	Vomiting
	Diarrhea
	Diuretics
1.2	Cause: Sodium substitution (still) more insufficient than water substitution
	Example: Inadequate therapy of isotonic dehydration
2	Hyponatremia combined with hypotonic hyperhydration
2.1	Cause: Redundant administration of water
	Examples: Intravenous application of solutions with low sodium concentration (water intoxication)
2.2	Cause: Decreased water excretion
	Examples: Heart failure
	Liver cirrhosis
	Renal insufficiency
	Nephrotic syndrome
	Syndrome of inappropriate ADH secretion
3	Hypernatremia combined with hypertonic dehydration
3.1	Cause: Insufficient water input
	Example: Thirst
3.2	Cause: Excessive water loss
	Examples: Diabetes insipidus
	Diabetes mellitus
	Diarrhea
	Excessive sweating
4	Hypernatremia with hypertonic hyperhydration
4.1	Cause: Sodium input inadequately high
	Example: Intravenous application of solutions with high sodium concentration
4.2	Cause: Sodium elimination decreased
	Example: Hyperaldosteronism

Modified from Külpmann WR, Stummvoll HK, and Lehmann P (1996) *Electrolytes: Clinical and Laboratory Aspects*. New York: Springer.

Sodium concentration depends mainly on the elimination and reabsorption of free water by the kidney; therefore, sodium disorders are often connected with water dysregulation or reflect its presence (Table 2).

In isotonic dehydration and isotonic hyperhydration, the sodium concentration is 'normal', and these conditions cannot be detected by sodium concentration measurement.

The osmolarity of serum ( $O_{\text{est}}$ ) can be estimated according to

$$O_{\text{est}} = 1.86[\text{Na}] + [\text{glucose}] + [\text{urea}] + 9 \quad [4]$$

where square brackets indicate the concentration of the analyte in  $\text{mmol l}^{-1}$ .

The osmotic gap is defined as the difference between osmolality, as determined by freezing point

**Table 3** Reference intervals ( $\text{mmol d}^{-1}$ ) for electrolytes in urine (adults)

Calcium	2.50–8.00
Chloride	85–170
Magnesium	2.50–8.50
Phosphate (inorganic)	11–32
Potassium	35–80
Sodium	30–300

depression, and calculated osmolarity ( $O_{\text{estim}}$ ). The osmotic gap is increased in pseudohyponatremia as well as in intoxication by ethanol or other compounds, which may be present in high concentration but are not considered in the formula. Thus, the osmotic gap can give an indication of a undetected intoxication. Sodium is filtered through the renal glomeruli ( $25\,000\text{ mmol d}^{-1}$ ), but 99% of the filtered sodium ions are reabsorbed in the tubular system. Therefore, fractional sodium excretion  $\text{FE}_{\text{Na}}$  is 1%. In disturbances of the tubular apparatus, sodium reabsorption is decreased and  $\text{FE}_{\text{Na}}$  is increased. In the case of renal hypoperfusion however, tubular reabsorption is increased and  $\text{FE}_{\text{Na}}$  is decreased. In intensive-care patients, measurement of urinary excretion of sodium (Table 3) may be necessary to monitor infusion therapy.

## Chloride

### Methods and Techniques

The favored method for the determination of chloride in serum and urine is potentiometry. The use of other techniques such as coulometry and UV-visible spectrophotometry is decreasing steadily. The determination of 'ionized' (free) chloride in serum or blood (extracellular water phase) becomes more popular by the introduction of combined blood gas/electrolyte analyzers.

**Coulometry** The basic information on the principle and practice of coulometry is presented elsewhere in this encyclopedia. In clinical chemistry, coulometry is exclusively used for the determination of chloride concentration. For this application coulometry is sufficiently specific, because the concentration of other halides is usually very low in comparison to the chloride concentration ( $\sim 100\text{ mmol l}^{-1}$  in serum). However, in case of long-lasting abuse of, e.g., hypnotics, which contain bromine (carbromal, bromisoval), bromide concentrations higher than  $5\text{ mmol l}^{-1}$  can be observed (bromide is eliminated very slowly (elimination half-life  $\sim 300\text{ h}$ ) and will accumulate). The bromide concentration will add

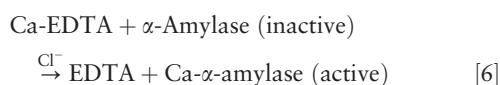

spuriously to the chloride concentration. Coulometry was considered to be adequately reliable for use as a reference method, albeit in a more elaborate procedure than that used in routine work. Unfortunately, because it is usually not part of a multichannel analyzer and highly mechanized coulometers are not available, coulometry can only be used for the measurement of a small number of samples.

**UV-visible spectrophotometry** (1) In this technique, the determination of chloride is performed mainly through the following reaction:

Thiocyanate ions are then detected by the addition of  $\text{Fe}^{3+}$ . The method can easily be mechanized for measurements on a large scale, but is subject to interference by bromide ions more than is coulometry. This method is no longer recommended, owing to the environmental hazards resulting from the mercury in the reagent.

(2) More recently, a method that uses the activation of  $\alpha$ -amylase by chloride has been proposed:

$\alpha$ -Amylase activity, which is proportional to chloride concentration, is determined by measuring the release of 2-chloro-4-nitrophenol from 2-chloro-4-nitrophenyl- $\beta$ ,D-maltoheptaoside. The method can be adapted to clinical chemistry analyzers, but is also susceptible to interference by bromide.

**Potentiometry** Silver chloride electrodes as well as membrane electrodes with ion exchange or ion carrier are used for chloride determinations. Measurements are usually performed with a highly diluted sample to obtain its chloride concentration. The measurement of chloride activity in undiluted samples is used more and more often, as it is easily performed by combined blood gas/electrolyte analyzers.

In solid-phase chemistry, chloride is also determined by potentiometry (Vitros, Ortho).

**Analytical reliability** The coefficient of variation (between days) should be less than 2% and the deviation from the target value should be less than 4% in a routine clinical laboratory to meet clinical requirements.

## Significance and Interpretation of Results

Chloride concentration measurement of serum (Table 1) is meaningful in the case of normal water concentration of the sample. In hyperlipemia or hyperproteinemia, 'pseudohypochloremia' occurs, because an increase of, e.g., 10% in the macromolecule-containing compartment decreases chloride concentration by 10%. A shift of 10% is especially important when the reference interval is relatively small. In the case of chloride, the upper limit of the reference interval differs from the lower limit by 11% (see Sodium above). The chloride concentration of serum therefore has to be readjusted (see Significance and Interpretation of Results above) when the water concentration is abnormal to be comparable with the reference interval.

The anion gap (AG) ( $\text{mmol l}^{-1}$ ) is calculated as

$$\text{AG} = [\text{Na}^+] - [\text{Cl}^-] - [\text{HCO}_3^-] \quad [7]$$

where  $[\text{Na}^+]$  is the sodium concentration in serum ( $\text{mmol l}^{-1}$ ),  $[\text{Cl}^-]$  is the chloride concentration in serum ( $\text{mmol l}^{-1}$ ), and  $[\text{HCO}_3^-]$  is the hydrogen carbonate concentration in serum ( $\text{mmol l}^{-1}$ ).

The reference interval of the anion gap is  $+8$  to  $+16 \text{ mmol l}^{-1}$ . The gap is due to the fact that the sum of the cations (e.g.,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ), which is not considered, is lower than the sum of the anions, which are excluded from the calculation (proteins, organic acids). The anion gap is enlarged in the cases of diabetic ketoacidosis, lactacidosis, and certain intoxications with salicylate, methanol (formate), ethanol (lactate), and ethylene glycol (oxalate, glycolate, glyoxylate). The anion gap is decreased or even becomes negative in the case of high bromide concentrations, especially if chloride concentration is determined by a method that is more sensitive to bromide than to chloride.

Sodium concentration and chloride concentration generally change in the same direction and to the same extent, whereas chloride and hydrogen carbonate change reciprocally (Table 4).

Urinary excretion of chloride (Table 3) usually resembles sodium excretion. In the case of metabolic alkalosis due to extrarenal loss of chloride, the excretion of chloride is  $<10 \text{ mmol d}^{-1}$ . If metabolic alkalosis is caused by mineralocorticoid excess, chloride excretion is unaffected and  $>10 \text{ mmol d}^{-1}$ .

## Potassium

### Methods and Techniques

Potassium in serum or urine may be determined by FAES, absorption spectrometry, or potentiometry

**Table 4** Disorders of chloride balance

1	Hypochloremia
1.1	Cause: Insufficient intake of chloride
1.2	Cause: Loss of chloride
	Examples: Vomiting
	Gastric lavage
	Metabolic alkalosis
	Respiratory acidosis
	Diuretics
1.3	Cause: Hypotonic dehydration (see Sodium)
1.4	Cause: Hypotonic hyperhydration (see Sodium)
2	Hyperchloremia
2.1	Cause: Excessive input of chloride
	Examples: Infusion of high amounts of chloride
	Uretersigmoidostomie
2.2	Cause: Decreased elimination of chloride (due to hydrogen carbonate loss)
	Examples: Diarrhea
	Pancreatic fistula
	Renal tubular acidosis
	Hypoaldosteronism with acidosis
2.3	Cause: Hypertonic dehydration (see Sodium)
2.4	Cause: Hypertonic hyperhydration (see Sodium)

Modified from Külpmann WR, Stummvoll HK, and Lehmann P (1996) *Electrolytes: Clinical and Laboratory Aspects*. New York: Springer.

(ISEs), which is most often used nowadays. Blood itself can only be used for analysis with potentiometry.

**Flame atomic emission spectrometry** Potassium concentration is determined at a wavelength of 767 nm using a propane flame. Procedures that take advantage of the lithium guideline technique are preferred (see Flame Atomic Emission Spectrometry above).

Good precision, accuracy, and specificity of FAES provide the reason for its choice as the basic principle of the potassium reference method. In routine work however, the use of FAES is steadily decreasing.

### UV-visible spectrophotometry

1. *Enzymatic determination:* In 1989, an 'enzymatic' method for the determination of potassium was proposed:

Potassium ions activate pyruvate kinase; its activity therefore reflects the potassium concentration. Interference by sodium is eliminated by binding to a kryptand, and that from ammonium ions by the addition of glutamate dehydrogenase.

2. *Kryptahemispherand determination:* The trinitroaniline-kryptahemispherand is used for the

measurement of potassium. This consists of an ionophor with a cavity fitting to the potassium ion and an attached chromophor. The absorption spectrum shifts on potassium binding. However, the method is subject to interference by lipids and bilirubin, which can be compensated for by the use of a sample blank.

Both the above procedures can be adapted to chemical analyzers.

**Potentiometry** The favored ISE for potassium determination uses valinomycin, an ion carrier of natural origin, in its ion-selective membrane. In undiluted samples an estimate of the concentration in the water phase is made, whereas in highly diluted samples the results reflect the concentration of the total sample. In hyperlipemia and hyperproteinemia or in hypoproteinemia, the results from undiluted samples will differ from diluted samples to the same extent as described above for sodium. As the 'relative' reference interval of potassium is much larger than that of sodium (the upper limit of the reference interval of potassium differs from the lower limit by 50%, and in the case of sodium by 7%), the effects are clinically less meaningful.

**Solid-phase chemistry** Potentiometry is used for potassium measurement also in solid-phase chemistry. Potassium is bound to valinomycin, releasing a proton that causes a color change in an indicator dye. In paraproteinemia, deviations from FAES values will occur.

**Analytical reliability** In routine work, the between-days coefficient of variation should be lower than 2.7%, with the deviation from the target value no more than 3.7% to meet clinical requirements.

### Significance and Interpretation of Results

The concentration of potassium in erythrocytes is 25-fold greater than in plasma. The analysis of hemolyzed samples therefore does not yield clinically meaningful results. Generally, any process that allows potassium to leave erythrocytes or thrombocytes, such as blood storage with or without visible hemolysis (in a refrigerator, no haemolysis), will falsify the potassium concentration. Even clotting of blood will increase potassium concentration; hence, its concentration is  $\sim 0.4 \text{ mmol l}^{-1}$  higher in serum (Table 1) than in plasma. Thrombocytosis or chronic myelosis may cause 'pseudohyperkalemia' as well as *in vivo* haemolysis. For these reasons, heparinized plasma is preferable to serum, as it decreases potassium release from cells.

**Table 5** Disorders of potassium balance

1	Hypokalemia
1.1	Cause: Insufficient input of potassium Examples: Chronic alcoholism Anorexia nervosa Infusion of potassium-depleted solution
1.2	Cause: Increased loss of potassium Examples: <i>Hormonally induced:</i> Mineralocorticoid excess <i>Renal loss:</i> Renal tubular acidosis Diuretics <i>Gastrointestinal loss:</i> Vomiting Diarrhea Abuse of laxatives
1.3	Cause: Shift from extra- to intracellular compartment Examples: Alkalosis Insulin
2	Hyperkalemia
2.1	Cause: Abundant potassium input Example: Infusion of excessive amounts of potassium Blood transfusion Potassium-containing drugs (e.g., potassium-penicillin)
2.2	Cause: Decreased potassium excretion Examples: <i>Hormonally induced:</i> Adrenal cortical hypofunction <i>Disturbed renal function:</i> Acute renal failure (oliguria) Chronic renal insufficiency Diuretics
2.3	Cause: Shift from intra- to extracellular compartment Example: Acidosis Lysis of cells (rhabdomyolysis, burning, treatment with cytostatics) Hyperthermia

Modified from Külpmann WR, Stummvoll HK, and Lehmann P (1996) *Electrolytes: Clinical and Laboratory Aspects*. New York: Springer.

Potassium concentration in plasma is dependent on renal function and acid–base balance. Mineralocorticoids promote the renal excretion of potassium, and insulin favors cellular uptake (Table 5).

Potassium is filtered through the glomeruli and is almost totally reabsorbed in the proximal tubules and Henle's loop. Therefore, potassium in urine (Table 3) stems from the secretion of the distal tubules and collecting ducts.

In hypokalemia due to renal loss, the urinary excretion of potassium is elevated; if the condition is due to extrarenal loss, elimination of potassium by urine is decreased ( $<10 \text{ mmol d}^{-1}$ ).

## Calcium

### Methods and Techniques

Calcium is determined in physiological samples by flame atomic absorption spectrometry (FAAS), FAES,

UV–visible spectrophotometry, and potentiometry. The last is primarily used for the measurement of 'ionized' (free) calcium ions in the (extracellular) water phase of blood or serum. The other techniques are used for the determination of total calcium in serum and urine. Urine must be acidified (pH 1) to release calcium ions from stable salts in the sediment.

**Flame atomic absorption spectrometry** FAAS measurements are performed at the calcium resonance line at 422.7 nm using an air–acetylene flame.  $\text{SrCl}_2$  may be used as the internal standard. Before analysis, samples are diluted and the viscosity of the analytical portion and of the calibrator solution is adjusted. Phosphate ions form thermally stable calcium salts, which then escape atomization and measurement. For this reason,  $\text{LaCl}_3$  is added, which binds phosphate ions enabling accurate calcium measurements independent of the (varying) phosphate concentration. FAAS is considered to be the most reliable technique for total calcium determination, and therefore it has been chosen as the reference method.

**Flame atomic emission spectrometry** Although FAES is not as reliable as FAAS, it was widely used because it allows the simultaneous mechanized determination of sodium, potassium, and calcium with adequate analytical performance for routine laboratory work. As calcium is not as easily excitable as the alkali metals, an air–acetylene flame ( $2325^\circ\text{C}$ ) instead of an air–propane flame must be used, which is less appropriate for the measurement of sodium and potassium. The flame spectrum of calcium has emissions at 422.7, 554, and 622 nm, the first being an arc line and the others being molecular bands. Usually 622 nm ( $\text{CaO}$ ) is chosen for measurement. Errors from anionic interference due to phosphate salts, which are not easily volatilized, can be excluded by the addition of phosphate ions in excess. For further details, see Sodium above.

**UV–visible spectrophotometry** Calcium ions form a violet-colored complex with *o*-cresolphthalein. Its absorbance is proportional to the calcium concentration of the sample and can be measured at 546 nm. Protein-bound calcium is released by hydrochloric acid. The interference of magnesium ions is excluded by the addition of 8-hydroxyquinoline. The method is in widespread use on mechanized analysers for clinical chemistry.

**Potentiometry** Potentiometry by ISEs is primarily used for the measurement of 'ionized' (free) calcium ions and not of total calcium concentration. The ion-selective membrane of the electrode contains an ion

carrier, e.g., ETH 1001. Sodium chloride is added to the calcium chloride of the calibration solution to adjust the ionic strength to  $160 \text{ mmol kg}^{-1}$ , which is equivalent to the mean ionic strength of serum. This procedure allows one to minimize the error, which stems from measuring activity and reporting concentration. Any factor that has an impact on activity and is different in the analytical portion from that in the calibration solution will increase the difference between the reported and the true concentration of free ions.

In all, 40% of calcium ions are bound to protein at pH 7.4 (Figure 2).

In alkalosis the bound fraction increases, and in acidosis the bound fraction decreases. If the concentration of free calcium ions at the actual pH is to be determined, blood samples have to be processed anaerobically and measured within minutes. Results are reported for the actual pH and for pH 7.4 after recalculating according to a suitable algorithm. If the pH is considered to be 'normal', serum can be used for measurement after readjustment of pH to  $7.4 \pm 0.2$  and recalculating for pH 7.4. Reporting at pH 7.4 is performed to allow for comparison with the reference interval, which is only known for this pH value. Determination of 'ionized' calcium by ISEs is preferred to calculation of its concentration from the values of total calcium, albumin, and pH using an empirical nomogram.

**Solid-phase chemistry** After application of the sample to the slide, calcium is released from protein

binding and penetrates the various layers to react finally with Arsenazo III, an indicator dye. The analytical performance of this solid-phase method is satisfactory, although systematic deviations from the reference method values have been observed with control sera (probably owing to special properties of their matrix).

**Analytical reliability** In routine clinical laboratories, imprecision between days for total calcium concentration measurements should be below a coefficient of variation of 3.0%, and deviation from the target value should not exceed 5% to meet clinical requirements.

**Significance and Interpretation of Results**

In all, 40% of calcium in serum is bound to protein and 10% to anions like citrate, hydrogen carbonate, etc.; 50% is 'ionized' (free) and only this fraction influences nervous excitability. Parathyroid hormone and calcitriol increase calcium concentration (Table 1); their antagonist is calcitonin. Input of calcium is by food, and output by incomplete tubular reabsorption of the glomerular filtrate and intestinal excretion (Table 6).

The determination of calcium in urine (Table 3) is usually of minor importance. In nephrolithiasis, the renal excretion of calcium is elevated in about one-third of all patients.

**Figure 2** Fractions of calcium in serum. (Modified from Siggaard-Andersen O, Thode J, and Fogh-Andersen N (1983) What is 'ionized calcium'? *Scandinavian Journal of Clinical Laboratory Investigation* 43: (Suppl. 165) 11–16.)

**Table 6** Disorders of calcium balance

1	Hypocalcemia
1.1	Cause: Insufficient input Examples: Calcium-depleted diet Reduced intestinal absorption (e.g., pancreatitis) Calcitriol deficiency
1.2	Cause: Excessive calcium loss Examples: Chronic renal failure Diuretics
1.3	Cause: Calcium binding exceeds calcium release Examples: Hypoparathyroidism Osteoblastic metastases
2	Hypercalcemia
2.1	Cause: Excessive calcium input Examples: Milk-Alkali syndrome Vitamin D intoxication

## Magnesium

### Methods and Techniques

Magnesium concentration can be determined in physiological samples such as serum and urine by FAAS, FAES, and UV-visible spectrophotometry. Urine must be acidified (pH 1.0) by hydrochloric acid to release magnesium from salts of the sediment. Recently, potentiometry has become available for the measurement of 'ionized' (free) magnesium in serum and blood.

**Flame atomic absorption spectrometry** The determination of magnesium by FAAS is performed in diluted samples using the resonance line 285.2 nm and a stoichiometric air-acetylene flame. The interference due to phosphate is eliminated by the addition of  $\text{LaCl}_3$ . FAAS is used for the most reliable determination of total magnesium in physiological samples and has been chosen as the basis for the reference method.

**Flame atomic emission spectrometry** Magnesium has a flame spectrum with a band emission with peaks at 370 nm and 383 nm and an arc line at 285.2 nm. Wavelengths of 370 nm or 383 nm have been proposed for FAES, but the method is only rarely applied.

### UV-visible spectrophotometry

1. *Xylidyl blue (Magon)*: Magnesium forms a colored complex with sulfonated Magon in a strongly basic medium. The absorbance maximum of the complex is at 548 nm. Calcium interference is avoided by the addition of ethylene-bis-(oxyethylene-nitrilo)-tetraacetic acid (EGTA) and interference by heavy metals by using cyanide.
2. *Other methods*: Calmagite, methylthymol blue, and Titan yellow are also used for the measurement of magnesium.
3. *Enzymatic determination*: The activity of glucokinase is dependent on the concentration of the Mg-ATP complex:

This method is not subject to interference by calcium ions. It is not widely applied because the reagents are rather expensive.

**Potentiometry** ISEs for the determination of 'ionized' (free) magnesium are now available. They use membranes with neutral ion carriers (e.g., modified ETH 5220), which, however, lack specificity with respect to calcium. Therefore, magnesium and calcium must be measured simultaneously in the same analytical portion (with different electrodes) and magnesium concentration is calculated from this.

**Solid-phase chemistry** Magnesium is released from protein, and penetrates the layers of the slide to react with a formazan dye. Calcium is bound to a chelating agent to prevent interference. Accuracy was less satisfactory with control sera than with native sera.

**Analytical reliability** The coefficient of variation for imprecision between days should be below 4% in the clinical laboratory, and the deviation from the target value should be below 7% to meet clinical requirements.

### Significance and Interpretation of Results

About 20–35% of magnesium is bound to proteins and other anions at pH 7.4, less in acidosis and more in alkalosis as discussed for calcium. As a variable amount of magnesium is bound, total magnesium concentration (Table 1) is only a poor estimate of free magnesium concentration, which is considered to be the biologically active fraction.

Magnesium is ingested with food, although only 50% is absorbed by the intestine. In the kidney, magnesium is filtered through the glomeruli and 95% is reabsorbed by the tubular apparatus. Increased secretion of mineralocorticoids and glucocorticoids promotes urinary excretion, owing to reduced tubular absorption (Table 7).

It is assumed that in European countries, the magnesium concentration of 'healthy' persons (reference interval) is lower than it should be because people at risk of myocardial infarction and angiopathy benefit from magnesium-supplementation to their diet. This low reference interval of magnesium concentration in serum is said to stem from magnesium-deficient soil. It is taken that the magnesium concentration should exceed  $0.8 \text{ mmol l}^{-1}$ .

The determination of magnesium in urine (Table 3) is helpful in the investigation of hypomagnesemia. If the urinary excretion is increased, hypomagnesemia is probably due to renal insufficiency. However, if the excretion is decreased, an extrarenal cause

**Table 7** Disorders of magnesium balance

1	Hypomagnesemia
1.1	Cause: Insufficient intake

must be assumed. Furthermore, a magnesium deficiency of the body, which at first may be accompanied by normomagnesemia, can be detected by a decreased excretion of magnesium in urine.

## Inorganic Phosphate

### Methods and Techniques

Inorganic phosphate concentration is determined, after an appropriate reaction, by UV–visible spectrophotometry. The methods are applicable to serum and urine, but not to blood.

#### UV–visible spectrophotometry

1. *Molybdenum blue*: Phosphate ions react with molybdate to form ammonium phosphomolybdate, which is reduced to convert it to molybdenum blue. Tin(II) chloride and ammonium iron(II) sulfate are used as reducing agents.

2. *Phosphorus–molybdate complex*: On reaction of phosphate ions with molybdate, the phosphorus–molybdate complex is formed. Its concentration is determined directly (without reduction) at 340 nm.

3. *Molybdivanadophosphate*: Phosphate concentration can be determined by reaction of the phosphate ions with vanadium molybdenum heteropolyacid (without reduction).

4. *Enzymatic determination*: Inosine and phosphate form hypoxanthine and ribose-1-phosphate in the presence of purine nucleoside phosphorylase. The amount of hypoxanthine is proportional to the phosphate concentration of the sample:

where PNP is purine nucleoside phosphorylase, XOD is xanthine oxidase, and POD is peroxidase.

**Solid-phase chemistry** Phosphate determination is performed by the use of the molybdenum blue complex.

**Analytical reliability** In routine clinical chemistry, imprecision between days should be below 5% (coefficient of variation), and the deviation from the target value should be below 8% to meet clinical requirements. Results are very high with some non-enzymatic methods owing to hydrolysis of organic phosphate esters.

### Significance and Interpretation of Results

After intake, phosphate (Table 1) is incompletely absorbed in the intestine. It is filtered through the glomeruli and 85% of the filtrate is reabsorbed in the tubular apparatus. Furthermore, phosphate is secreted into the intestine and is excreted with the feces. Parathyroid hormone increases the renal elimination of phosphate, whereas calcitriol, somatotropin, and insulin inhibit urinary excretion by increasing tubular reabsorption (Table 8).

Urinary excretion (Table 3) of phosphate is dependent on (1) the amount that is filtered through the glomeruli and the fraction thereof that is reabsorbed in the (proximal) tubular system, (2) the intake of phosphate by food, and (3) the metabolism of bone.

This is why the determination of phosphate excretion in daily urine is clinically not very meaningful and should be supplemented by measurements of (1) phosphate clearance, (2) fractional tubular phosphate reabsorption, and (3) maximum tubular phosphate reabsorption.

## Hydrogen Carbonate or Total CO<sub>2</sub>

### Methods and Techniques

Total CO<sub>2</sub> or hydrogen carbonate (bicarbonate) is determined in serum by UV–visible spectrophotometry

**Table 8** Disorders of phosphate balance

1	Hypophosphatemia

or potentiometry. In urine, these analytes are measured by titrimetry or manometrically. They can be calculated for the extracellular water phase of blood by using of quantities obtained in blood gas analysis.

### UV-visible spectrophotometry

1. In continuous-flow analysis, CO<sub>2</sub> gas is released by acidification of the analytical portion. It diffuses across a silicon-rubber membrane into an alkaline hydrogen carbonate buffer. The gas is converted into hydrogen carbonate and hydrogen ions; this causes a pH change, which is monitored by a pH indicating dye. The color change of the dye is measured by spectrophotometry and is proportional to total CO<sub>2</sub> of the sample.

2. In an enzymatic method, all CO<sub>2</sub> forms are converted to HCO<sub>3</sub><sup>-</sup> by the addition of alkali, which reacts with phosphoenolpyruvate:

where PC is phosphoenolpyruvate carboxylase and MD is malate dehydrogenase.

**Potentiometry** For the determination of hydrogen carbonate, lactic acid is added to release CO<sub>2</sub> from HCO<sub>3</sub><sup>-</sup>; CO<sub>2</sub> is measured by a pCO<sub>2</sub> electrode.

**Solid-phase chemistry** A potentiometric test is available for the determination of total CO<sub>2</sub> in serum by the use of ISEs sensitive to the carbonate ion.

**Calculation** Actual bicarbonate and total CO<sub>2</sub> are usually calculated in clinical chemistry from blood gas analysis.

*Actual bicarbonate:*

$$\log \text{HCO}_3^- = \text{pH} - \text{pK}' + \log p\text{CO}_2 + \log \alpha_{\text{CO}_2} \quad [12]$$

HCO<sub>3</sub><sup>-</sup>, hydrogen carbonate concentration in blood (mmol l<sup>-1</sup>); pK', apparent pK of CO<sub>2</sub> in blood (6.095); pCO<sub>2</sub>, partial pressure of CO<sub>2</sub>; α<sub>CO<sub>2</sub></sub>, molar solubility coefficient of CO<sub>2</sub>.

*Total CO<sub>2</sub>:*

$$\text{CO}_2 = \alpha_{\text{CO}_2} \cdot p\text{CO}_2 + [\text{HCO}_3^-] \quad [13]$$

α<sub>CO<sub>2</sub></sub>, Bunsen coefficient (0.0307); pCO<sub>2</sub>, partial pressure of carbon dioxide (mmHg); [HCO<sub>3</sub><sup>-</sup>], hydrogen carbonate concentration (mmol l<sup>-1</sup>).

**Analytical reliability** It has been proposed that deviations from the target value must be lower than the following: pH: ±0.03; pCO<sub>2</sub>: ±3 mmHg (or ±7.5%) (College of American Pathologists).

### Significance and Interpretation of Results

It must be ascertained that serum was obtained from blood that was processed anaerobically during sampling and centrifuging. Total carbon dioxide comprises dissolved CO<sub>2</sub> (3%), hydrogen carbonate (64%), and carbamino derivatives of plasma proteins (33%). Hydrogen carbonate is increased in metabolic alkalosis and decreased in acute and chronic acidosis. Hydrogen carbonate concentration (Table 1) is needed for the calculation of the anion gap (see Chloride above).

Hydrogen carbonate in urine is determined in addition to urinary titratable acid and ammonium for the estimation of the net excretion of hydrogen ions:

$$[\text{H}^+] = [\text{TA}] + [\text{NH}_4^+] - [\text{HCO}_3^-] \quad [14]$$

where TA is titratable acid.

The [H<sup>+</sup>] excretion is decreased in chronic renal insufficiency.

## Emerging Needs

Techniques that are currently available for the measurement of physiological samples are sufficiently reliable for routine patient care. However, they are not yet adequately precise to monitor intraindividual changes. For this purpose, improvement of accuracy must be achieved.

To alleviate medical interpretation, it is hoped that the measurement of the 'ionized' (i.e., free) fraction of the electrolytes by ISEs in undiluted samples will become the widespread technique. At the moment, the use of these methods is restricted because they are still less practical (with regard to sample volume and throughput) than traditional procedures, which measure total concentration. The improvement of practicability will anyhow be the focus of future developments to allow quick measurements at all times at low costs.

The *in vivo* monitoring of electrolytes in blood by ISEs may be achievable in the near future. Although this is an interesting new perspective for research, an urgent and widespread need for use in patient care is not yet evident.

The measurement of electrolytes in blood cells is under investigation, but on the whole the results are not too promising. There is evidence that the serum concentration of some electrolytes poorly reflects the electrolyte concentration in the tissues. Therefore, devices are that enable the measurement of electrolytes *in vivo* in muscle or bone are required.

## Introduction

An important parameter in biochemistry and medical diagnostics is the concentration of glucose in biofluids, which is most frequently determined in the

clinical laboratory. For routine analysis the established methodology uses different enzymatic assays involving photometric or electrochemical detection. New trends strive for reagentless assays using biosensor technology. Another important research field concerns the development of self-monitoring devices for blood glucose, necessary for patients suffering from diabetes mellitus.

D-Glucose is by far the most abundant monosaccharide in physiological samples. It has two stereoisomers designated the  $\alpha$ - and  $\beta$ -anomeric forms. In aqueous solution each form changes slowly, by

means of the free aldehyde form, into an equilibrium mixture of approximately one-third  $\alpha$ -D- and two-thirds  $\beta$ -D-glucose (mutarotation). This is detectable as a change in the optical rotation due to the different optical activities of the two anomeric forms. These anomers may exhibit dissimilar properties in enzymatic reactions:

Since blood serves as the primary metabolic transport system between the body organs, its composition is the preferred indicator with regard to the pathophysiological condition of the patient. This is the reason why most determinations are concerned with whole blood or biofluids derived from it. Glucose in urine is also an index component of metabolic disorders in patients. Other biological fluids have been considered as an alternative assay for blood glucose.

The aldohexose glucose is a substance of high metabolic importance, since it can be considered as the main energy carrier in the human organism. Regulation of its concentration is extremely crucial because the metabolism of some organs, such as brain and kidney, and also erythrocytes, depend on it. Under physiological conditions the glucose concentration in mammalian blood varies as a result of nutritional and metabolic activities. There are, however, endocrine feedback mechanisms in the body to regulate the blood glucose concentration. An important role in lowering the glucose level is played by the insulin secreted by the  $\beta$ -cells of the Langerhans islet cells in the pancreas. In addition to insulin, the hormones glucagon, epinephrine, and cortisol take part in regulating the blood glucose concentration.

The quantification of glucose is a prerequisite for the diagnosis and therapy of patients suffering from disorders in their carbohydrate metabolism that are mainly caused by diabetes mellitus. In type I diabetes, the  $\beta$ -cells have been destroyed, leading to a severe insulin deficiency. In type II diabetes, enough insulin may be available, but there is an insulin resistance in the target organs.

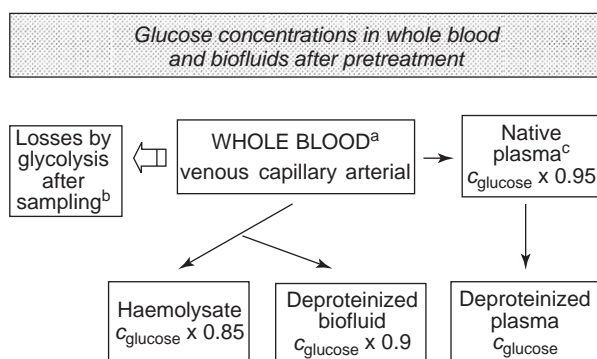

In therapy, the aim is always towards a blood glucose concentration comparable with that of metabolically healthy individuals (normoglycemia). For type I diabetics the external administration of insulin

is required, as insulin deficiency can lead to severe hyperglycemia, ketosis, coma, and death. However, the application of insulin and thus the regulation of blood sugar concentration are rather imperfect, although with intensified conventional insulin therapy supported by self-monitoring devices for blood glucose improvement can be gained. Patient kits with test strips have been developed based on dry chemistry. Urine testing was considered as the only way to obtain day-to-day control before blood-sugar tests were available. The presence of abnormal glucose concentrations in urine indicated a blood glucose level above the renal threshold, resulting in urinary excretion of glucose.

The technology currently available still delivers inadequate glycemic control, even for diabetic patients undergoing intensive insulin therapy. A close connection between late diagnosis or poor stabilization of diabetes mellitus and the development of late complications leading to large vessel and microvascular diseases is evident. The reasons for this are the long-term effects of pathological hyperglycemia. Severe hypoglycemia also has drastic consequences and can lead to unconsciousness. For effective control of blood glucose level through insulin administration, frequent blood glucose monitoring is mandatory. At present, research activities involve the development of reliable glucose biosensors that could be used for an artificial endocrine pancreas. Other applications concern, for example, *in vitro* analyzers and biomedical research.

## Methods and Techniques

Many different assays are available for glucose, and are distinguishable by their sample preparation and detection techniques. In routine clinical practice, analysis is usually of plasma or serum. Preparation of these samples requires centrifugation of the cellular blood components (hematocrit) for plasma and coagulation of proteins for serum. There can be specific problems, such as the stability of blood samples due to the glycolytic activity of the red and white blood cells, unless precautions are taken by using additives such as sodium fluoride, dilution in a hypotonic buffer, or immediate centrifugation. Hemolysed blood as a specimen is rather popular, since time-consuming deproteinization and centrifugation can be avoided. Another advantage is the stability of glucose in such a sample having been treated by the addition of a solution of digitonin and maleimide, by which the erythrocyte membranes are destroyed and glycolytic enzymes are deactivated. For some assays, however, deproteinization of the sample is essential.

**Figure 1** Variations in blood glucose assay results (100% value for deproteinized plasma by definition): <sup>a</sup>Arterio-venous differences depend on nutritional and physiological conditions. <sup>b</sup>Losses of plasma glucose at room temperature without preservatives by 0.2 (0.02) and 0.33 (0.06) mmol l<sup>-1</sup> per hour in blood from adults and newborns, respectively (values in brackets for blood on ice, see Lin YL, Smith CH, and Dietzler DN (1976) Stabilization of blood glucose by cooling with ice: An effective procedure for preservation of samples from adults and newborns. *Clinical Chemistry* 22: 2031–2033); effect of additives has been described by Landt M (2000) Glyceraldehyde preserves glucose concentrations in whole blood specimens. *Clinical Chemistry* 46: 1144–1149; <sup>c</sup>glucose concentrations in plasma are usually ~15% larger than in whole blood (see also Colagiuri S, Sandbæk A, Carstensen B, *et al.* (2003) Comparability of venous and capillary glucose measurements in blood. *Diabetic Medicine* 20: 953–956).

The actual concentration of glucose in blood differs from that in fluids that are derived from whole blood (see **Figure 1**). The concentrations for plasma are ~15% higher than for the original specimen due to a lower glucose concentration within the red blood cells. For deproteinized samples, the volume-displacement effect from separated proteins is relevant. Glucose concentrations in capillary blood samples tend to be slightly higher when compared with those from venous blood, especially after meals, with differences of up to 2 mmol l<sup>-1</sup>. For stationary conditions, as found for fasting subjects, the concentration difference is significantly reduced.

For tissue measurements, an appropriate pretreatment is necessary to allow for thorough cell disintegration and sample homogenization. Dilution of the sample fluid is advisable to reach the linear concentration range of the assay. When photometry is used for detection, sample preparation must result in a clear and colorless solution.

There are certain requirements for the analysis of glucose. The assays used should be rather selective for this monosaccharide and provide high sensitivity and linearity. For clinical laboratories, in particular, the methods require levels of accuracy and precision as set by the guidelines of professional organizations.

The assays should be preferably suitable for all kinds of physiological samples and measuring devices whether manual or mechanical, and applicable in routine analysis, emergency, or research laboratories. Further considerations are the cost factor and simplicity of the method.

Glucose methodology can be classified into several categories. Enzymatic procedures currently dominate clinical assays. However, before these were developed, classical chemical methods were widespread. In recent years, methods based on different spectroscopies have also been introduced.

### Chemical Methods

Although glucose possesses some aldehyde characteristics, it lacks others, e.g., due to the formation of the predominant cyclic hemiacetal in neutral or weakly acidic solutions, when forming two different monomethyl derivatives under conditions that normally convert an aldehyde to a dimethyl acetal. However, its reduction potential can be utilized. For many years qualitative testing of glucose in urine relied on this property using Tollens' reagent (Ag(I) → Ag), Nylander's reagent (Bi(III) → Bi), or freshly prepared Fehling's solution (Cu(II) → Cu(I)). Many modifications for quantitative work were carefully worked out based on the Fehling method.

In another popular chemical method, hexacyanoferrate(III) is reduced to hexacyanoferrate(II), and the unchanged Fe(III) can be quantitatively determined, e.g., by iodometric back-titration with sodium thiosulfate. Modifications have been proposed to allow direct photometric quantification. Other titrimetric methods have also been proposed, for example, using an iodometric method with vanadium(V) in perchloric acid as reagents. The simple reduction methods are regarded as nonspecific due to the interference of other similar compounds with reducing properties.

A useful chemical and rather selective method involves *o*-toluidine, leading to a colored reaction product, glycosylamine, which is photometrically determined at 630 nm; however, aldo-pentoses and aldo-hexoses, such as mannose and galactose, interfere. This method had been adapted for use in automatic analyzers. It had been favored due to its simplicity and reliability, but severe limitations occurred when the reagent used was classified as carcinogenic.

### Enzymatic Methods

In clinical chemistry, enzymatic methodology clearly dominates quantitative analysis, and most glucose biosensors are nowadays based on immobilized

enzyme technology. The reasons for this are the high selectivity and the simplicity of the assays, with possible implementation on analyzers. Different measurement techniques can be taken into account: in comparison with end-point methods, automated kinetic procedures with readings at fixed-time yield much shorter analysis times and, for some assays, a reduced sensitivity to interferences. A prerequisite is that the overall reaction follows pseudo-first-order kinetics with respect to glucose. For glucose determination three main enzyme systems are available, which are described in detail.

**Hexokinase (HK; EC 2.7.1.1) and glucose-6-phosphate dehydrogenase (G-6-P-DH; EC 1.1.1.49)** The determination of deproteinized samples is carried out according to the following reactions. For both enzymes, the presence of magnesium ions is required

for their catalytic activity:

In the first reaction, a phosphate group from ATP (adenosin triphosphate) is transferred to the substrate with the formation of ADP.

The second, so-called indicator reaction, provides the specificity of the method, since hexokinase also converts other hexoses, such as D-fructose and D-mannose, into their phosphorylated compounds. The formation of the coenzyme NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate) can be measured photometrically, preferably at the absorption band maximum at 340 nm (see Figure 2). The hexokinase method has been internationally recommended as a reference method.

In addition, a fluorescence method has also been described, leading to a detection limit more than 10 times lower than that of the absorbance method. A further reduction, down to femtomolar concentrations, can be achieved by coupling the hexokinase procedure to a bioluminescent indicator reaction using firefly luciferase.

**Glucose dehydrogenase (G-DH; EC 1.1.1.47)**

An advantage here is the single reaction step, after which the lactone produced is spontaneously hydrolyzed to give gluconic acid. The addition of mutarotase accelerates the interconversion of the anomeric  $\alpha$ -form into the  $\beta$ -anomer. Quantification by photometry is the same as for the preceding method. Because only D-xylose and mannose, found at rather low concentration levels in physiological fluids, cause interference in clinical specimens (see also Table 1), this method is widespread and accepted for the determination of glucose due to its

**Figure 2** UV absorption spectra of NAD, NADP, and their reduced forms used for photometry in enzymatic glucose assays.

**Table 1** Reaction rates of different carbohydrates by glucose-dehydrogenase relative to  $\beta$ -D-glucose (100%)

Substrate	Relative rate	Substrate	Relative rate
2-Deoxyglucose	125	Cellobiose	1
2-Amino-2-deoxy-D-glucose	31	D-Ribose	0.8
D-Xylose	15	Lactose	0.7
D-Mannose	8	2-Deoxyribose	0.1
6-Amino-6-deoxy-D-glucose	6	D-Galactose	0.0

simplicity and speed. The reagents for this method are commercially available from several companies as an assay kit. Analysis of body fluids is possible either without or with prior deproteinization by means of, e.g., perchloric acid/perchlorate solution; even hemolysate from capillary blood can be used directly. Excellent correlations with the hexokinase method have been reported.

Alternatively, electrochemical detection by using an amperometric biosensor has been proposed using modified electrodes for the electrocatalytic oxidation of the reduced cofactors (NADH, NADPH). The oxidation current reflects the rate of glucose conversion. Additionally, covalent coupling of the coenzyme is a precondition of more advanced reagentless measuring devices. Further developments use an electron mediator such as ferrocyanide and PQQ/PQQH<sub>2</sub> (pyrroloquinoline quinone) as the cofactor pair.

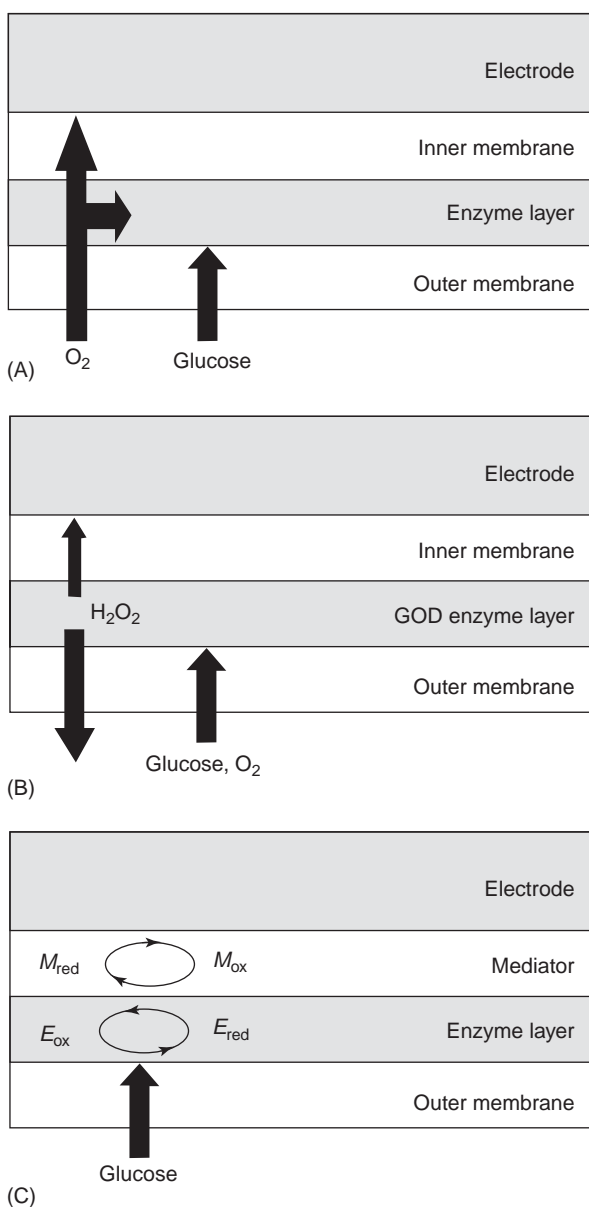

### Glucose oxidase (GOD; EC 1.1.3.4)

This enzyme reaction dominates the glucose assays. Usually, an indicator reaction is used which can be followed spectrophotometrically. In one such reaction the hydrogen peroxide produced reacts with phenol and 4-aminophenazone in the presence of peroxidase to give a colored dye. Other combinations have been proposed that have been adapted for several automatic analyzers.

Other detection procedures follow oxygen consumption by a so-called Clark amperometric oxygen electrode, which is thought to be the first biosensor combining electrochemistry and immobilized enzymes (see **Figure 3**). Alternatively, the formation of hydrogen peroxide can be monitored amperometrically. The removal of interferences from various reducing substances, e.g., ascorbic and uric acids, paracetamol, and others is a prerequisite for selectivity. One method of removing interferences uses a hydrogen peroxide-permeation selective membrane to screen out electrochemical interferences from biological fluids, so that the enzyme layer is sandwiched between permeable membranes. A recent approach employs a scavenging microreactor for preoxidation of interfering substances.

A significant extension of the utilization of amperometric probes could be obtained by electron transfer mediators. The idea is to replace oxygen by an alternative redox couple, allowing a rapid reaction of the reduced enzyme with the mediator, which shuttles electrons efficiently between electrode and

**Figure 3** General approaches for *in vivo* monitoring of glucose by different enzyme electrodes. enzyme. A high selectivity by a pH-independent and low oxidation potential is desirable. One of the most successful mediator compounds is ferrocene (bis-(cyclopentadienyl) iron) and its derivatives. Based on this technology, credit-card and pen-sized devices have been introduced for patient self-monitoring of blood glucose and clinical emergency use (see **Table 2**). The instruments, with a response time down to

15 s, utilize small, disposable electrode strips. Several studies have been devoted to their response to different  $\text{O}_2$  partial pressures. For the reaction above, oxygen is needed to reoxidize the reduced enzyme-cofactor complex (glucose oxidase/FADH<sub>2</sub>) and for producing hydrogen peroxide. In the case of an electron mediator, oxygen is competing for reoxidation of FADH<sub>2</sub>.

The performance of the handheld meters matches the best test systems currently available, but still cannot compete with standard laboratory devices. It must be noted that the instruments should be handed out only to patients trained in the use of the meter to achieve the necessary testing quality. In the analytical instrument market, analyzers based on enzymatic electrochemical technology dominate. A summary of the performance of some commercially available devices with regard to linearity, coefficient of variation, sample frequency, etc., is presented in **Table 3**.

There are so many variants of enzymatic assays that they cannot be listed here completely, but fiber-optic biosensors must be mentioned. The so-called optodes employ immobilized indicators in combination with optical fibers and some kind of spectroscopic detection. **Figure 4** shows schematically an oxygen optode used for glucose sensing with fluorescence detection. Another category includes fiber-optic sensors based on bio- and chemiluminescence, which can give picomolar detection limits. A chemiluminescent reaction, for example, can be coupled to the production of hydrogen peroxide by using luminol. The ultrasensitivity of such assays has great attractions for the design of novel biosensors, in particular, as they allow miniaturization and simple instrumentation. As one of the latest developments, multiple-analyte biosensor chips have been designed based on electro-chemiluminescent measurements. For glucose, such biosensors utilize the reaction of the hydrogen peroxide produced by the GOD enzyme and electrochemically oxidized luminol, both immobilized on microbeads. The photons emitted are measured by a charge-coupled device (CCD) camera, leading to a detection range of  $20 \mu\text{mol l}^{-1}$  to  $2 \text{ mmol l}^{-1}$ .

### Dry Chemistry

The first major upsurge in dry chemistry took place with the introduction of the Ames Clinistix (Miles, USA) in the 1950s for the testing of urinary glucose. The test strips utilized the oxidation of  $\beta$ -D-glucose as catalyzed by glucose oxidase with hydrogen peroxide formation and subsequent oxidation of a chromogen impregnated on a paper matrix to a colored compound. The approach has subsequently been

**Figure 5** Schematic diagram of a solid phase reagent system for glucose measurement (Ektachem System).

extended to other biofluids such as plasma and whole blood. The development was made possible by application of different technologies. The Ektachem system (Eastman Kodak Co, Rochester, NY, USA), for example, is shown schematically in Figure 5. All

reactions are carried out on a multilayer system similar to a photographic film. The serum or plasma droplet is placed on to a spreading layer. A multilayered reagent zone is below the reflective area filled with pigments such as  $\text{TiO}_2$  or  $\text{BaSO}_4$ . The chemical reaction products can be evaluated visually or by using a small device, which measures diffuse reflectance. The analyte concentration is mostly calculated relative to a reflectance standard using some signal linearization. Systems have also been developed to deal with whole blood that may be wiped off or remain on the test strip.

The availability of reagent strips and pocket-sized reflectance meters has had a great impact on the management of diabetes allowing for intensified therapy. There are many different devices on the market, which are clearly challenged by the novel electrochemical testing equipment described above. Dry chemistry has made significant contributions to clinical chemistry, in particular in the area of rapid diagnostics for point-of-care testing or self-monitoring of blood glucose by patients with diabetes, at the cost of slightly reduced reliability compared with standard methods. Instrumentation ranges in size from hand-held instruments, as for dedicated blood glucose analysis (see **Table 2**), to bench-top systems such as the Reflotron<sup>®</sup> Plus from Roche Diagnostics (Mannheim, Germany), which are capable of handling more than one analyte with a specific module for each test. Similar analysis slides are manufactured and sold by Johnson & Johnson for their Vitros analyzer (see also <http://www.vitros.com>).

### Automation in the Clinical Laboratory

For managing today's clinical testing workloads, automation is a prerequisite. Besides the general chemistry testing for glucose and further compounds, fully automated and computer controlled analyzers are capable of quantifying many additional parameters (electrolytes, therapeutic drugs, and others) in various biofluids such as serum, plasma, urine, and cerebrospinal fluid samples. However, some floor-model instrumentation may be restricted only to, for example, critical care clinical chemistry parameters. Usually, random access sample handling is included, and the frequency of tests can reach 800 and more per hour. A user interface enables loading of samples in racks or carousels, of controls, reagents, and wastes. The essential instrumental parts are concerned with efficient transport fluidics and robotics and further processing units as needed for agitation, mixing, measurement, etc. Carryover between samples is tightly controlled and achieved with small volumes of cleaning solutions. Photodiode-array

detectors with discrete wavelengths or interference filters have been mainly used for photometry. On the other hand, compact analytical devices incorporating one-parameter dedicated biosensors, able to produce either discrete or discontinuous electronic signals related to individual analytes, have also been designed for routine analysis as discussed above.

### In Vivo Monitoring

The basic components of an artificial pancreas are the blood glucose sensor and an automated and possibly implantable insulin pump with a 'closed loop' regulating process for insulin administration. For clinical applications, two developments – either based on optical methods or enzymatic–electrochemical approaches for glucose detection – must be noted. They led to extracorporeal monitoring devices that were connected through a double-lumen catheter to a peripheral vein for realizing a continuous, buffer diluted blood flow. Early attempts for a bedside artificial pancreas resulted in the Biostator (Miles Laboratories, Elkhart, IN, USA). The apparatus offered promising perspectives for clinical research programs, but the original therapeutic intention, i.e., optimization of insulin therapy in diabetic patients, could not be satisfactorily reached. Nevertheless, experience from the application of such instrumentation accelerated the efforts in the development of paracorporeal and intracorporeally applicable devices and implantable sensors for blood glucose determination under daily life conditions.

Nowadays, the intensive care discipline is especially interested in continuous monitoring or at least in frequent analysis of glycemia (point-of-care testing). Intensive insulin therapy in critically ill patients can thus be realized when it is necessary to 'clamp' their glucose concentration between 4.5 and  $6.4 \text{ mmol l}^{-1}$  for improving their long-term outcome.

**Implantable biosensors** In contrast to conventional laboratory analyzers and extracorporeal bedside devices, where any sample can be adapted to the needs of the sensing element by means of dilution, centrifugation, addition of chemicals, and other preparation steps, an intracorporeal sensor has to meet certain conditions to function under the natural environment of the surrounding biological medium. Furthermore, the sensing element and the ancillary electronics for signal amplification and processing must be miniaturized, and – at least for sensors with a limited lifetime – be mass-producible, easily applicable, and exchangeable, as well as affordable for the patient. Although several principles can be used to

realize glucose measurements intracorporally, most enzymatic biosensors employ electrochemical detection, but a few approaches using optical detection by infrared (IR) spectrometry or polarimetry also exist.

Many biosensors are now widely used for *in vitro* measurements, but implantable devices have been reported to possess only limited functionality due to inflammatory tissue reaction. Intravascular monitoring is particularly hampered by thrombotic deposition on the sensing element and further associated complications. From the alternative approaches, the direct implantation of a needle-type sensor into the subcutaneous tissue is often favored. Further requirements for the sensors are nontoxicity and sterilizability without loss of enzyme activity. An important prerequisite for the long-term application of such devices is the biocompatibility of the cover membranes. Special materials such as 2-methacryloyloxyethyl phosphorylcholine, polyethylene oxide-based hydrogels, or Nafion<sup>®</sup> have been shown to give satisfactory short-period results. Using the latter membrane, the interference from ascorbic acid can also be eliminated. Extensive research work has been carried out by many groups to develop membranes for long-term bio-stability.

An essential difference between any extracorporeal or laboratory measuring method and sensors in the body is the lack of cleaning of the measuring element. Thus, the continuous exposure of an intracorporally implanted sensor to the body tissue leads to protein build-up on its diffusion membranes and finally to a hypovascular foreign body capsule, resulting in unpredictable changes in the diffusion characteristics toward the biosensor surface. Experimental studies in animals as well as in humans have demonstrated that continuous glucose measurements over some days or weeks by means of subcutaneously implanted biosensors are at least possible.

**Microdialysis devices** Another interesting option to realize continuous or at least frequent glucose measurements is based on microdialysis. Comparable with a conventional double lumen catheter, the microdialysis cannula has a small dialysis membrane or a hollow fiber with a well-defined recovery of body fluid on the tip of the catheter. In most cases, microdialysis probes have been placed subcutaneously to allow compounds of low relative molecular mass such as glucose from the interstitial fluid to penetrate the dialysis membrane by diffusion. By means of a continuous or discontinuous flow of buffer solution, the harvested glucose, depending on the recovery through the membrane, will be diluted and transported to an extracorporeal measuring device. Compared with direct implantation, this extraction

technique significantly eases constraints that arise from sensor poisoning due to the elimination of proteins of molecular mass above the membrane cutoff. It allows pocket-sized instrumentation with the sensing device, usually an amperometric enzyme electrode, to be placed outside the body. Compared with bedside analyzers using diluted blood, the main advantage of the microdialysis sampling is the very small amount of interstitial fluid needed. This even allows application in children. Such systems have been used in the intensive care of neonates and after surgical operations for safeguarding patients against hypo- and hyperglycemia, especially after experiencing severe traumatic brain lesions and stroke.

However, a disadvantage, caused by the small sample volume, the needed length of the catheters, and the slow flow velocity of the buffer/sample mixture, is the time lag between sampling and detection. When adding up diffusion time, flow time, and response time of the measuring system, the lag time is usually ~15 min. To avoid long delay times, the need for small and low dead volume measuring devices is evident, and optimized devices with a total delay time of <3 min have been reported. Thus, microdialysis-based systems are suited for monitoring tasks and for measuring controlled therapeutic steps – even during rapid glucose dynamics.

Finally, there have been many investigations into the glucose concentration profiles in blood and subcutaneous tissue, or to be precise, within the interstitial fluid. Changes in the blood are transmitted to the subcutaneous tissue with a delay of 5–10 min, so that glucose homeostasis is possible by using, for example, a needle-type sensor, although the ‘gold standard’ is still set by the glucose concentration in capillary blood.

**Minimal-invasive technology** Other novel strategies such as minimal-invasive techniques, e.g., the so-called GlucoWatch biographer (Cygnus, Redwood City, CA), have been recently evaluated. The sensor is wearable like a watch, and an intermittent glucose analysis is carried out every 20 min by employing reverse iontophoresis through the skin for biofluid collection. The lifetime of the glucosensor is 12 h, and furthermore a skin preconditioning for 3 h is essential for quasi-continuous measurements, especially for hypoglycemia alert. With another approach, interstitial fluid is collected through an array of micropores created with a laser in the outer horny skin layer and measured in a patch containing a glucose sensor. For noninvasive techniques, refer to spectroscopic methods below.

## Spectroscopic Methods

**Polarimetry** With spectroscopic techniques the interaction of matter with electromagnetic radiation is evaluated. From the optical activity mentioned already, a rapid polarimetric method for glucose can be derived, which is of considerable technical importance, although it is subject to interference from other optically active compounds. The aqueous humor of the eye has been investigated for use in monitoring applications. Using the optical rotation of the *in vitro* humor, a correlation with blood glucose has been established. However, problems due to the time lag in the different concentration profiles and instrumentation for *in vivo* measurements remained unsolved (for a rabbit's eye used as a test model, a time lag of 5 min was determined when drastic changes in blood glucose concentration occurred). Micro-degree polarimetry using diode lasers with visible and near-IR radiation have recently received attention. For improving the method selectivity, multi-wavelength approaches have been tested in the past.

**Infrared spectroscopy** IR spectroscopy is a widely applied technique for obtaining quantitative results on a great variety of substances, but still rarely found in the clinical laboratory despite the recent progress observed for novel assay technologies. The technique is based on the wavelength- and concentration-dependent absorption of IR radiation by the molecules under study and can provide a simultaneous, continuous, and reagentless determination of many analytes. In principle, compounds participating in the enzymatic reactions of glucose can also be monitored. However, advances in direct spectrometry have yielded a significant contribution to analytical chemistry in the biomedical field. With the advent of multivariate calibrations with multi-wavelength information, the technique has become tremendously successful within the field of routine analysis and process control. The new challenge presented by biomedical applications is the low concentration range of compounds to be monitored against an extremely large and varying background.

The mid-IR spectral range contains much denser and more selective information compared to the near-IR, where overtone and combination bands of the fundamental molecular vibrations occur. As the intensity of bands in the mid-IR is higher, optical path lengths are on the micrometer scale. Such path lengths can be achieved with a special technique that uses attenuated total reflection, and which renders optical materials compatible with aqueous biofluids. Recently, dry films of biosamples of nanoliter volumes have been successfully applied for reagent-free

quantification. In the near-IR, cuvettes normally have millimeter path lengths due to smaller sample absorptivities.

Several extensive studies have investigated the prospects of clinical assays for glucose, as well as other substrates, in human plasma or whole blood. The intra-assay variation coefficients using large hospital sample populations for validation reached less than 5%. Since reference methods are needed to provide calibration standards, their imprecision can influence assay results significantly, as has been found for glucose. Using near-IR radiation, which is of great interest because of its potential for noninvasive glucose monitoring in tissue, quantitative results were slightly worse when studying plasma sample populations by multivariate near-IR spectrometry.

Different approaches have been proposed to achieve noninvasive *in vivo* monitoring of glucose, which is desirable for a variety of reasons (as already discussed under section: *In vivo* Monitoring). There are two alternatives: probing of subcutaneous tissue by using diffuse reflectance with radiation of wavelengths  $\sim 1.6 \mu\text{m}$ , where significant glucose absorption exists, or by using spectrometry within the so-called therapeutic window with wavelengths  $\sim 1.0 \mu\text{m}$ , which renders a feasible transmission measurement, e.g., of a finger tip, or exploits the glucose concentration-dependent scattering within skin tissue. It is hoped that acceptable equipment meeting the demands of patient self-monitoring blood glucose devices can be developed soon. Only a few results with calibrations against capillary blood glucose have been published so far. Reliability is achieved only for hyperglycemic concentrations, because average prediction errors for glucose have been found to be just below  $2 \text{ mmol l}^{-1}$ , which is still unacceptable for normal and hypoglycemic ranges.

**Raman spectroscopy** The Raman effect involves inelastic radiation scattering that provides molecular spectral fingerprints with similar, but often complementary spectral information to mid-IR spectroscopy. Therefore, also a simultaneous reagent-free measurement of multiple analytes is possible. An advantage is the weak water Raman spectrum, contrary to the intensive water absorption bands in the IR spectrum. Recently, glucose measurements in various biofluids such as plasma and even whole blood have been pursued, but interference from strong fluorescence of matrix substances or photo-decomposition of the sample by intensive laser radiation has hampered the studies. Therefore, most recent research has been carried out using near-IR excitation Raman spectroscopy, thus avoiding water and other biosample absorbers. However, tremendous trade-off

due to lower Raman intensities is found for longer wavelength excitation, compared with excitation with UV-visible lasers. Despite this, intensive excitation sources such as diode lasers and extremely sensitive detectors, e.g., silicon-based CCDs, are available for miniaturized spectrometer systems. More research will be needed for routine implementation of Raman spectroscopy based assays.

**Fluorescence spectroscopy** A promising technique for *in vitro* and *in vivo* assays of glucose involves the sensitive detection of fluorescence emitted by compounds that have absorbed radiation from an external monochromatic source. Because of their simplicity and sensitivity, glucose-specific fluorescence probes have been designed in the past, e.g., involving the binding of glucose to a protein such as concanavalin A. In a competitive assay, the fluorescence resonance energy transfer (FRET) is used between a fluorescent donor and an acceptor, each covalently linked to the protein or a dextran polysaccharide. In the absence of glucose, the binding between the protein and dextran leads to a high FRET efficiency, while the presence of glucose causes competitive binding, thus reducing the FRET effect. Preliminary *in vivo* tests with skin-implanted poly(ethylene glycol) microspheres, containing such a transcutaneously probed fluorescent compound pair, have been reported.

**NMR spectroscopy** Nuclear magnetic resonance (NMR) spectroscopy is an important technique for the study of biological fluids and intact cells. Compared with other analytical methods, it is nondestructive and noninvasive. For carbohydrates, only the proton ( $^1\text{H}$ ) NMR spectroscopy is relevant, although phosphorylated compounds have been measured using  $^{31}\text{P}$  NMR spectroscopy. So far, the measurement of biosamples is complicated by the water resonance that obscures a large portion of the spectrum, thus creating a dynamic range problem during data acquisition. With high-field NMR spectrometers, however, using special pulse sequences, high-resolution spectra can be obtained from physiological fluids such as blood plasma and, for example, red blood cells with concentrations of glucose at the  $\text{mmol l}^{-1}$  level. Detection limits reported are in the order of  $0.01\text{--}0.1\text{ mmol l}^{-1}$  for small molecules, allowing the study of intracellular glycolytic chemistry. For glucose in blood plasma a coefficient of variation of better than 4% has been reported and accuracy is generally within 5% of a clinical glucose oxidase method. The  $^1\text{H}$  NMR spectroscopic method cannot compete with, for example, enzymatic methods on a routine basis, due to spectrometer and

measurement complexity, but it shows its potential for applications needing simultaneous multicomponent analysis, especially for carbohydrates and their metabolites.  $^{13}\text{C}$  NMR can provide spectra of plasma glucose with isotopically enriched compounds, which are necessary because of the low NMR sensitivity and the low natural abundance of  $^{13}\text{C}$ .

**Positron emission tomography** With this technique, radioactive nuclides that emit positrons during decay are administered. The positrons interact with an antiparticle, the electron of a neighboring molecule. This event causes two  $\gamma$  photons to be emitted in opposite directions that can be detected by two separate detectors. This allows the assessment of three-dimensional images. For glucose to be doped, the  $^{11}\text{C}$  labeled compound must be synthesized. As this technique allows the investigation of biodynamic processes, for example, glycolytic rates, it has been successfully used for the measurement of regional cerebral or myocardial glucose metabolism in human subjects. These applications of a complex, but noninvasive method, provide insights into the functional physiology of the human brain unmatched by any other currently known method.

**Mass spectrometry (MS)** For *in vitro* glucose analysis, MS has been used in combination with gas chromatography (GC). As demonstrated in several studies, isotope dilution mass spectrometry can offer an analytical method of high accuracy and precision. In order to evaluate routine methods, reference methodology is needed. Great demands on analytical performance are required to get a 'definitive method' accepted. After adding  $^{13}\text{C}$  labeled glucose to the sample, glucose is separated from the matrix and derivatized to allow combined capillary GC-MS. The ratio of certain peaks areas, specific for normal and  $^{13}\text{C}$  labeled glucose (selected ion monitoring), are evaluated for quantification for sample and calibration standards. By use of a standard serum reference material, a relative accuracy of  $\sim 0.5\%$  has been established; values slightly below this can be achieved for the coefficient of variation as a precision parameter (within-day and between-day imprecision). Results achieved for determining glucose in whole blood were slightly larger (mean of 1.0% for within-run coefficients of variation).

Recently, matrix-assisted laser desorption/ionization (MALDI) MS of carbohydrates has found much interest, since it also enables the study of underivatized compounds. Besides methods for sample preparation and for extracting carbohydrates from biological media, various MALDI matrices were compared in a recent review.

An interesting field is the determination of the glucose turnover rate in human subjects. With the advances in MS instrumentation, rates can be measured using stable isotopes, and are a prerequisite for studying dynamic aspects of glucose metabolism. For this purpose, 6,6-dideuteroglucose is a suitable tracer, but recent results for studying glucose kinetics within intravenous glucose tolerance tests were also obtained using  $^{13}\text{C}$  labeled glucose. Glucose oxidation rates can be determined by administering uniformly  $^{13}\text{C}$  labeled glucose and analyzing the  $^{13}\text{C}$  enrichment of exhaled carbon dioxide. In this case, an isotope-ratio mass spectrometer is used. Other kinetic metabolic parameters, such as glucose carbon recycling and production rates, can be detected by mass isotopomer analysis of plasma  $^{13}\text{C}$  glucose, which overcomes the problems of measuring the low  $^{13}\text{C}$  isotopic abundance in plasma glucose. One limitation, however, is the rather high cost of the tracer.

### Separation Techniques

The use of GC was mentioned in the preceding section. It requires, prior to sample injection into the GC column, some sample cleanup and derivatization to produce volatile species. Several different derivatives, such as penta-trimethylsilyl derivative, aldono-nitrile acetate, diacetone glucose, and others, have been suggested allowing the separate determination of the two anomeric species. For mass spectrometric detection, the reaction of D-glucose with *n*-butylboronic acid (BBA) followed by acetic anhydride leading to a quantitative conversion to glucose-BBA can be utilized. A fused silica capillary column coated with SE-54 may be considered for separation of different aldohexoses.

The use of high-performance liquid chromatography (HPLC) for the analysis of carbohydrates has increased, as different column materials have become available. Water–acetonitrile mixtures are needed for partitioning on amine-bonded silica phases, whereas ion chromatography with anion or ligand exchange separation modes allows the use of water as the mobile phase. One advantage of HPLC is that the aqueous carbohydrate sample can be injected directly into the column and mono-, di-, and oligosaccharides can be separated in a single step. This method is important for the analysis of glycoproteins after hydrolysis. Detection can be via a refractive index or an optical rotation detector as referred to in the section ‘Polarimetry’. Since spectrophotometry offers only poor sensitivity for carbohydrates, postcolumn derivatization is required for fluorescence measurements. Other postcolumn reactions combine immobilized

enzyme reactors with amperometric or luminol chemiluminescence detection.

Pulsed amperometric detection (described below) delivers selective and sensitive measurements, also allowing gradient elution in HPLC. This detection technique has been a great breakthrough in carbohydrate analysis.

Capillary electrophoresis is another high-efficiency analytical technique that currently has significant impact as a tool for bioanalytical research. This separation technique is advantageous with respect to small sample volumes, rapid analysis, large resolution power, and low costs, thus making it ideal for the analysis of numerous endogenous substances in biofluids. Analysis of sugars at high pH needed for conversion to ionic species, with electrochemical detection, is a promising approach for separation. Recent developments have led to the use of microchip electrophoresis, with a total analysis time of 1 min, suited for clinical glucose assays. UV and fluorescence detection is also possible, but needs postcolumn derivatization for chromophore tag appendage. With amperometric detection, a linear response for glucose has been reported for the range of 10–1000  $\mu\text{mol l}^{-1}$ .

### Electrochemical Detection

Monosaccharides, for example, undergo direct electro-oxidation at modest positive potentials using noble metal electrodes, e.g., gold or platinum, but the electrode surface is poisoned by oxidation products, although the poisoning can be eliminated by oxidative desorption. The latter produces a metal oxide layer, which is reduced back by a negative potential to restore electrode activity. Detection limits with pulsed amperometric detection are  $\sim 10$ –50 pmol. A similar electrocatalytic sensor can be exploited for *in vivo* monitoring of glucose. Adjustments to the potential sequence at an appropriately membrane-covered electrode have been necessary to reduce interference from endogenous oxidizable substances such as urea, ascorbic acid, and others, or from ethanol and pharmaceutical compounds. Another technique is achieved by using constant potential amperometric detection with working electrodes of transition metals (Cu, Ni), which needs only simple instrumentation with detection limits of 20  $\text{nmol l}^{-1}$  reported for glucose.

### Significance and Interpretation of Results

In the clinical laboratory, the most frequently found samples are of blood or fluids derived from whole

**Table 4** Reference fasting concentration intervals for glucose in capillary blood plasma samples (compiled from various references)

Subject	Range ( $\text{mmol l}^{-1}$ )
Adults	3.8–6.4
Children between 2 and 16 years	3.8–5.8
Children within 2nd year	3.3–5.5
Babies after 1st month, within 1st year	2.2–5.0
Newborns within 1st month	1.6–3.3

blood. Differences in glucose concentration between such specimens, which are specific for sample preparation and blood origin, have already been mentioned. Since the biologically significant glucose is found in the arterial vessels, often capillary blood samples are analyzed. For adults, physiological regulation mechanisms usually keep the blood glucose level between 2.5 and  $7.3 \text{ mmol l}^{-1}$ . Concentration values lying outside this range are grounds for further investigation. Reference intervals as statistically defined by using a population of healthy individuals are presented in Table 4. No differences between female and male subjects have been observed. For children, the ranges are generally shifted to lower values. Neonatal hypoglycemia has been suggested below  $1.1 \text{ mmol l}^{-1}$  for the newborn of low birth weight and, for normal newborns, below  $1.6 \text{ mmol l}^{-1}$  from birth until the fourth day.

The oral glucose tolerance test (see Figure 6) is the most commonly used test for diagnosis of diabetes mellitus and impaired glucose tolerance. There have been suggestions for standardization, especially with concern for the oral administration of the glucose load (aqueous solution of 75 g of glucose in 500 ml), and criteria for interpretation. The normal values for fasting plasma glucose are below  $6.1 \text{ mmol l}^{-1}$ , whereas the normal 2-h postload blood glucose concentration has been defined to be  $<7.8 \text{ mmol l}^{-1}$ . A glucose concentration level over  $11.1 \text{ mmol l}^{-1}$  after 2-h postadministration indicates the existence of diabetes, in particular with increased glucose concentration for the fasting subject above  $7.0 \text{ mmol l}^{-1}$  (all values for capillary whole blood). A fasting concentration level below the latter value, but between 7.8 and  $11.0 \text{ mmol l}^{-1}$  during the tolerance test, indicates an impaired glucose tolerance. Another type of metabolic disorder is gestational diabetes that can occur during pregnancy. Initial screening employs the following diagnostic criterion of a fasting plasma glucose  $>7.0 \text{ mmol l}^{-1}$ .

The normal renal threshold is between 9 and  $10 \text{ mmol l}^{-1}$ , but may show some individual scatter. At this level, glucose is spilled over into the urine, resulting in a more or less strong correlation of blood

**Figure 6** Glucose time dependence for an oral glucose tolerance test of a diabetic (trace A) and a healthy subject (trace B). Time is after glucose intake. The administration of insulin is usually not performed, but exemplifies the difficulties in control of blood glucose, since the hypoglycemic range is reached later. The central unshaded area shows schematically the normal and tolerated concentration ranges for subjects undergoing this test.

and urine glucose concentrations. As the concentration of several constituents varies in this body fluid, the excreted glucose values are usually stated on a per day basis (the average daily urine volume of adult subjects is  $\sim 1.5 \text{ l}$ , but can vary significantly). The reference range here has been defined up to  $2.8 \text{ mmol}$  per day. Concentrations above  $55 \text{ mmol l}^{-1}$  have been measured in urine samples of diabetic patients. Below the renal threshold, slightly larger urine glucose concentrations outside the physiological range can occur, indicating an impaired glucose tolerance as a sign for a developing diabetes or renal failure.

Another, but less frequently monitored body fluid is the cerebrospinal fluid. However, its concentration profile is important for neurodiagnostics. The glucose concentration is  $\sim 60\text{--}80\%$  of the blood level with concentration profiles delayed due to diffusion by  $\sim 4 \text{ h}$ . The reference interval is between 1.1 and  $4.4 \text{ mmol l}^{-1}$ .

Saliva has received much attention; because it is easily sampled, the correlation of the glucose concentration therein, to that in blood, has been studied in detail. A glucose level in parotid saliva for fasting subjects has been found to be between 5 and  $30 \mu\text{mol l}^{-1}$ . After consumption of carbohydrates, concentration increases by factors of two to four have been noticed. However, correlation between the concentrations of glucose in plasma and saliva is rather poor due to other factors influencing the salivary glucose concentration. Blood testing is still essential for biomedical diagnostics and, in

particular, for blood glucose self-monitoring by diabetic patients.

## Trends in Glucose Methodology

Biosensors are currently en vogue and their development rapid; and a new field of synthetic receptors has been established recently. Miniaturization of biosensors can be done on the basis of nano- and microfabrication technology, and mass production will make them inexpensive and disposable. Self-contained analytical devices of small size, which respond selectively and reversibly to the concentration of a compound in a biological sample, still attract many researchers. Nowadays, third-generation glucose meters are even equipped with fully developed quality control and patient data management. In particular, much interest is also shown in bio- and chemiluminescence detection in novel biochip technology or in combination with intracellularly applicable nanobeads due to their extremely low detection limits for glucose.

Innovative research has also led to interesting novel instrumentation, e.g., the development of needle-type sensors for the simultaneous monitoring of glucose and insulin. Other detection schemes have been realized, for example, with disposable biosensors employing a glucose-sensitive biochemomechanical gel, i.e., the pH-dependent gel shrinkage depends on glucose oxidase enzyme activity and glucose concentration. Assays with colorimetric glucose recognition have also been developed, for which glucose assembles special functional groups into a supramolecular complex (photonic crystal hydrogel with changes in the diffraction of visible light). A different detection technique has been used by Di-setronic Medical Systems' scientists. They exploit viscosity changes within a sensitive liquid, consisting of a macromolecular Dextran with terminal glucose residues and Concanavalin A, which is a glucose-specific lectin and links the Dextran into a highly viscous gel. Free glucose weakens the cross-linking with the result of a measurable viscosity reduction.

For the clinicians, other aspects are more important. Although for the last few years many predictions of a breakthrough in the field of biosensors have been made, a satisfactory system for long-term continuous *in vivo* glucose monitoring is not yet available. In this context, *in vivo* calibration of such sensor systems is still an issue. The two different approaches, either invasive methodology using electrochemical detection or noninvasive monitoring by spectroscopic techniques, may be successfully applied for diabetes therapy in the not too distant

future, although regular controls by means of standard assays for the determination of glucose in blood and urine will still be required.

### Introduction

#### Creatine and Creatinine

Creatine can be synthesized in the body from glycine, arginine, and methionine. Creatine can also be obtained from eating meat. There is ~120 g of creatine in the body of an average adult male, with a turnover rate of  $\sim 0.016 \text{ day}^{-1}$  for creatine. Vegetarians have actually been shown to have somewhat lower levels of creatine in their urine and serum than nonvegetarians. Over 90% of creatine in the body is found in the muscles, where it is converted to phosphocreatine in a reversible reaction with adenosine triphosphate (ATP), mediated by creatine kinase. When ATP is depleted during exercise, the ADP so formed is rephosphorylated in a reaction with the phosphocreatine. Phosphocreatine and creatine cyclize non-enzymically to form creatinine, which is then excreted by renal glomeruli and not reabsorbed by tubules. The amount of creatinine excreted in the urine is related to the amount of phosphocreatine present in the body, and is indicative of lean muscle mass. In a 24 h period, the amount of creatinine excreted is fairly constant for a particular subject. Thus, concentrations of other components of the urine may be normalized to the creatinine concentration. The clearance rate of creatinine is an important clinical diagnostic tool. For example, decreased excretion of creatinine is a symptom of muscle degeneration. Thus, the analysis of creatinine in urine is routine, and in a clinical setting is usually done on an automated system. Creatinuria can be an indication of a muscle-wasting disease such as muscular dystrophy, or be a result of creatine supplementation. Many athletes, body builders, and young males in general take creatine as a supplement to increase their muscle bulk and to increase their endurance during

resistance training. They typically start with a 5 day loading phase of ~20 g creatine per day. Much of this is excreted in the urine in the first 5 h after its ingestion. Creatine is found at low concentrations in the plasma and at higher concentrations in erythrocytes. Erythrocyte creatine concentrations decrease with the age of the cell and thus can be used to determine cell age. The role of the creatine in erythrocytes has not been defined, but the concentration can be increased by creatine supplementation.

Creatinine can be analyzed in automatic colorimetric analyzers using the Jaffe method, by gas chromatography–mass spectrometry (GC–MS) after derivatization, or simultaneously with creatine by high-performance liquid chromatography (HPLC) or capillary electrophoresis (CE). Enzyme-based methods for both creatine and creatinine are used for colorimetric analyses as well as in biosensors. Creatine can be converted to creatinine to be analyzed by the Jaffe reaction. Fluorescence analyses and methods involving partial least squares (PLS) with ultraviolet (UV), infrared (IR), or near-infrared (NIR) spectra can also be used.

#### Sarcosine

Sarcosine, or *N*-methyl-glycine, is an amino acid that forms as an intermediate in the metabolism of choline in the kidney and liver. It is formed by the methylation of glycine using *S*-adenosylmethionine and the enzyme *N*-methyltransferase. It is normally present in very low concentrations compared to other amino acids unless the subject is suffering from sarcosinemia. This is not a well-defined syndrome, but subjects often exhibit neurological problems. The cerebrospinal fluid of patients with Parkinson's disease and multiple sclerosis contains higher than normal levels of sarcosine.

Sarcosine is also formed in the hydrolysis of creatine mediated by creatine amidinohydrolase (creatinase). This reaction is used in a variety of sensors for creatine and creatinine.

Sarcosine can be analyzed by various amino acid analyses, although in some cases the detection limits

detection of choline, glucose, glutamate, lactate, lysine and urate. *Biosensors and Bioelectronics* 19: 433–439.

When ATP is depleted during exercise, the ADP so formed is rephosphorylated in a reaction with the phosphocreatine. Phosphocreatine and creatine cyclize non-enzymically to form creatinine, which is then excreted by renal glomeruli and not reabsorbed by tubules. The amount of creatinine excreted in the urine is related to the amount of phosphocreatine present in the body, and is indicative of lean muscle mass. In a 24 h period, the amount of creatinine excreted is fairly constant for a particular subject. Thus, concentrations of other components of the urine may be normalized to the creatinine concentration. The clearance rate of creatinine is an important clinical diagnostic tool. For example, decreased excretion of creatinine is a symptom of muscle degeneration. Thus, the analysis of creatinine in urine is routine, and in a clinical setting is usually done on an automated system. Creatinuria can be an indication of a muscle-wasting disease such as muscular dystrophy, or be a result of creatine supplementation. Many athletes, body builders, and young males in general take creatine as a supplement to increase their muscle bulk and to increase their endurance during

resistance training. They typically start with a 5 day loading phase of ~20 g creatine per day. Much of this is excreted in the urine in the first 5 h after its ingestion. Creatine is found at low concentrations in the plasma and at higher concentrations in erythrocytes. Erythrocyte creatine concentrations decrease with the age of the cell and thus can be used to determine cell age. The role of the creatine in erythrocytes has not been defined, but the concentration can be increased by creatine supplementation.

Creatinine can be analyzed in automatic colorimetric analyzers using the Jaffe method, by gas chromatography–mass spectrometry (GC–MS) after derivatization, or simultaneously with creatine by high-performance liquid chromatography (HPLC) or capillary electrophoresis (CE). Enzyme-based methods for both creatine and creatinine are used for colorimetric analyses as well as in biosensors. Creatine can be converted to creatinine to be analyzed by the Jaffe reaction. Fluorescence analyses and methods involving partial least squares (PLS) with ultraviolet (UV), infrared (IR), or near-infrared (NIR) spectra can also be used.

#### Sarcosine

Sarcosine, or *N*-methyl-glycine, is an amino acid that forms as an intermediate in the metabolism of choline in the kidney and liver. It is formed by the methylation of glycine using *S*-adenosylmethionine and the enzyme *N*-methyltransferase. It is normally present in very low concentrations compared to other amino acids unless the subject is suffering from sarcosinemia. This is not a well-defined syndrome, but subjects often exhibit neurological problems. The cerebrospinal fluid of patients with Parkinson's disease and multiple sclerosis contains higher than normal levels of sarcosine.

Sarcosine is also formed in the hydrolysis of creatine mediated by creatine amidinohydrolase (creatinase). This reaction is used in a variety of sensors for creatine and creatinine.

Sarcosine can be analyzed by various amino acid analyses, although in some cases the detection limits

only allow sarcosine to be detected in the serum of subjects with sarcosinemia. The best known amino acid analysis involves separation on a cation exchange column followed by derivatization with ninhydrin for detection by absorption. Sarcosine can also be derivatized and determined by liquid chromatography (LC) with absorption or fluorescence detection, or by GC with either flame ionization or mass spectrometric detectors. A biosensor has been made based on sarcosine oxidase immobilized in nafion, with amperometric detection.

Creatine, creatinine, and sarcosine can be analyzed simultaneously by 500 MHz proton nuclear magnetic resonance (NMR).

### Properties of Creatine, Creatinine, and Sarcosine

The structures of creatinine, creatine, and sarcosine are shown in Figure 1. The  $pK_a$  values for creatinine are 4.8 and 9.2, for creatine are 2.6 and 14.3, and for sarcosine are 2.21 and 10.12.

Creatine and creatinine are in equilibrium with each other, but at room temperature at close to neutral pH the interconversion is slow. Conversion of creatine to creatinine is essentially complete if the solution is boiled in the presence of acid, while creatinine in basic conditions forms creatine. These conversions are not normally a problem during clinical analysis. In alkaline solutions of urine with high creatinine concentrations, conversion rates of  $\sim 5\%$  per hour may be found.

The absorbance of creatine is insignificant above 225 nm, but increases at lower wavelengths. It is generally monitored at 210 nm. Creatinine absorbs strongly at 210 nm, and slightly less strongly at 230 nm. Both wavelengths can be used for its determination. Uric acid and urea also absorb at these wavelengths. The absorptivity of urea is very low, although it may still cause slight interference because of its high concentrations.

**Figure 1** Structures of creatine, creatinine, and sarcosine.

### Reference Values

The normal range for serum creatinine is  $4\text{--}16\text{ mg l}^{-1}$  ( $35\text{--}140\text{ }\mu\text{mol l}^{-1}$ ). During kidney dysfunction this concentration may increase to  $1000\text{ }\mu\text{mol l}^{-1}$ . Values above  $140\text{ }\mu\text{mol l}^{-1}$  indicate that renal function needs further assessment. Values above  $530\text{ }\mu\text{mol l}^{-1}$  are indicative of severe renal problems. In urine,  $0.5\text{--}3.3\text{ g per day}$  is normally excreted.

Creatine concentrations in serum are generally less than  $5\text{ mg l}^{-1}$ . Increases are seen in muscle wasting, hyperthyroidism, and after supplementation.

The reference values for erythrocyte creatine are  $228\text{--}550\text{ }\mu\text{mol l}^{-1}$  for males and  $258\text{--}598\text{ }\mu\text{mol l}^{-1}$  for females. In urine, normal creatine concentrations range up to  $150\text{ mg per day}$ ; values as high as  $12\text{ g per day}$  are found when subjects are supplementing with creatine.

The reference values for sarcosine in urine are  $2\text{--}20\text{ }\mu\text{mol per day}$ , and in serum sarcosine concentrations of  $0.50\text{--}2.70\text{ }\mu\text{mol l}^{-1}$  are usual. In most analyses, sarcosine is just not detected in normal serum. In patients with sarcosinemia, the concentrations range up to  $603\text{ }\mu\text{mol l}^{-1}$  in serum and  $9.4\text{ }\mu\text{mol mg}^{-1}$  creatinine in urine.

### Sample Preparation

The presence of proteins in biological fluids constitutes an interference in many analyses and their removal is often the major part of sample preparation. Proteins are typically removed by precipitation with acetonitrile or sulfosalicylic acid. Ultrafiltration or ultracentrifugation can also be used.

The protein content of urine and cerebrospinal fluid is much lower than that of blood, and dilution is often the only sample treatment necessary. However, protein removal is necessary before reversed-phase column chromatography to protect the lifespan of the column. Sample dilution helps reduce the presence of proteins, but even running untreated urine samples diluted 50-fold can very quickly destroy a column.

## Absorption Methods

### Creatinine

In a clinical lab, creatinine is normally determined using a commercial analyzer utilizing an absorption method based on the Jaffe reaction. In the Jaffe reaction, creatinine is reacted with alkaline sodium picrate solution to form an orange creatinine-picrate complex. The absorbance at 510 nm can then be measured after a specified reaction time (endpoint method). There are, however, a variety of modifications to the basic method because of the positive

interference from species such as protein, glucose, ascorbic acid, and the ketone bodies (pyruvic, acetoacetic,  $\beta$ -hydroxybutyric, and acetone). The interference can be of the order of 20% in normal serum or plasma and higher if the subject is diabetic. The interference can also be higher in erythrocytes. Surfactants are sometimes incorporated in the reagent mix, or the reaction is monitored as a function of time (kinetic method). Cleanup of a sample on an ion-exchange column is effective but not practical for an automated procedure. One method that works well, and is used in some commercial kits, is acidification to pH 4 after the initial complex formation. The color due to complexed creatinine is destroyed, while that produced by interferences remains. The difference in the absorbance at 500 nm is proportional to the concentration of creatinine. The incorporation of dialysis in an automated flow method can also reduce interference.

*Note:* Picric acid is a strong oxidizing agent and is explosive when dry, so spills should be treated accordingly.

The second most common method used in automated analyzers is based on the use of enzymes to produce a compound that will react with a substance provided to form a colored product. For example, creatinine iminohydrolase (creatinine deiminase) catalyzes the conversion of creatinine to *N*-methylhydantoin and ammonia. This reaction can be carried out in a flow injection analysis system setup so that the ammonia diffuses into an acceptor stream containing a pH indicator; the color changes of which are measured by diffuse reflectance.

Creatinine amidohydrolase hydrolyzes creatinine to creatine, the creatine is hydrolyzed to sarcosine, urea by creatine amidohydrolase, and sarcosine oxidase catalyzes the breakdown of the sarcosine to glycine, formaldehyde, and peroxide. When horseradish peroxidase is included, the reduction of peroxide can be coupled with various compounds to produce absorbing species. One example of a suitable chromogen is 3,5-dichloro-2-hydroxybenzenesulfonic acid-4-aminophenazone, with the absorbance being measured at 510 nm.

Creatinine can also be determined by measuring the rate of disappearance of NADH after addition of creatinine amidohydrolase, creatine kinase, pyruvate kinase, and lactate dehydrogenase.

Although there are less interferences in the enzyme-based methods, the higher cost has prevented them from replacing the Jaffe method, although there are a number of commercial systems based on them. The limit of detection (LOD) is  $1 \text{ mg l}^{-1}$ .

Mid-IR and near-IR methods have been used in conjunction with PLS methods to determine

creatinine and other metabolites in blood and urine. The use of dry films solves the problem of water interference.

### Creatine

Traditionally, creatine has been determined by the Folin method whereby creatine is determined as creatinine by the Jaffe reaction after conversion in boiling acid for an hour, or autoclaving for 20 min at  $120^\circ\text{C}$ . Thus, one aliquot of a sample is analyzed for creatinine, and a second part is heated in acid prior to creatinine analysis. The difference between the two answers gives the concentration of creatine. Large errors are often reported. Also note that heating creatine for an hour in  $6 \text{ mol l}^{-1}$  HCl is reported to liberate sarcosine.

One reagent that has been used for the automated analysis of creatine is diacetyl-1-naphthol. However, some creatine is converted to creatinine during acid hydrolysis, and corrections must be made.

The preferred absorption-based methods are those based on enzyme-catalyzed reactions. The absorbance of NADH (340 nm) after addition of creatine amidohydrolase, sarcosine oxidase, formaldehyde dehydrogenase, and  $\text{NAD}^+$  to a creatine-containing solution is proportional to the concentration of creatine present. Creatinine amidohydrolase produces creatine from creatinine. Thus, any assays for creatinine which use creatinine amidohydrolase in the first step can be used for creatine by just leaving out that first step. Conversely, creatine can interfere in those analyses, although creatine is normally present in substantially lower concentrations than creatinine.

Creatine can be analyzed in diluted urine by a PLS method using UV absorption analysis, after calibration with a training set of urine samples analyzed using HPLC. The determination of creatinine in this way is not as reliable.

## Fluorescence

### Creatine

The fluorescence of a ninhydrin derivative of creatine can be used to determine creatine concentrations in blood and urine. Protein and arginine are precipitated by treatment with barium hydroxide and zinc sulfate, and after addition of ninhydrin the solution is made basic and the fluorescence excited at 390 nm is monitored at 495 nm. Creatinine and phosphocreatine do not form fluorescent derivatives, but some guanidine compounds can interfere, although they are not normally present in significant amounts.

Urine samples must be pretreated with anionic exchange resin to remove unidentified interfering species that are not a problem when analyzing blood.

### Sarcosine

Sarcosine is a secondary amine and reacts with fluorescamine at pH 12 to give a nonfluorescent aminoenone. Subsequent reaction with the primary amine (L-Leu-L-Ala) for 10 min at 70°C produces a pyrolinone that can be excited at 390 nm to fluoresce at 480 nm. Unreacted fluorescamine is rapidly hydrolyzed at pH 12 and thus does not interfere by reacting with the primary amine. The LOD is  $\sim 10 \mu\text{mol l}^{-1}$ .

### Biosensors

Sensors for creatine, creatinine, and sarcosine generally involve the use of enzymes (Table 1) and can be based on potentiometry or amperometry.

#### Creatinine

Because tests for creatinine are routine in a clinical setting, there has been much work done on devising sensors for creatinine in urine, serum/plasma, and hemodialysate. Such sensors would allow point of care (POC) testing which is becoming more common in places such as emergency departments. Some commercial POC analyzers are already available. A typical one such as an i-STAT<sup>®</sup> is handheld, with the blood sample being placed on a cartridge for insertion. The sensor (microfabricated thin film electrode) is calibrated automatically by means of an internal standard solution immediately before each analysis. The NOVA 16 benchtop analyzer incorporates determinations of  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , glucose, urea

nitrogen, and hematocrit along with the analysis of creatinine.

To create a potentiometric creatinine sensor, creatinine iminohydrolase, which catalyzes the production of ammonia from creatinine, can be immobilized on the surface of an ammonium ion selective electrode. There is no interference from creatine but some from the ammonium ions in blood and urine.

Another biosensor is based on an ion-sensitive field-effect transmitter. Creatinine iminohydrolase is immobilized on the gate by cross-linking with bovine serum albumin in glutaraldehyde vapor. Creatinine iminohydrolase catalyzes the formation of *N*-methylhydantoin (and ammonia) from creatinine. The differential signal between a reference and sensing chip is proportional to creatinine concentration.

#### Creatine and Creatinine

When the three-enzyme sequence based on creatinine amidohydrolase is used, any creatine present can interfere with the determination of creatinine, so two sensors are used: one to determine the total creatine plus creatinine and one to determine just creatine (by only using creatine amidinohydrolase and sarcosine oxidase). Creatinine is determined by difference. Amperometric sensors are generally based on this sequence and do not suffer from interferences. They are usually designed to respond to peroxide, though some have used oxygen electrodes. Typically, Pt electrodes are used. A sensor for just creatine only requires the creatine amidinohydrolase and sarcosine oxidase sequence.

One configuration that can be used to amperometrically detect the peroxide produced from the oxidation of sarcosine is a Pt working electrode, a Ag/AgCl reference electrode, and a carbon counter electrode screen-printed onto a polyester sheet. The enzymes can be immobilized on the working

**Table 1** Enzymes used for the analysis of creatine and creatinine, including the final species detected

Creatine amidinohydrolase	Sarcosine oxidase	Horseradish peroxidase		Benzoquinone-imine

electrode in a poly(carbamoyl sulfonate) hydrogel. The working electrode is first coated with a polymer such as nafion to exclude interfering substances. In a more elegant design, the enzymes are dissolved in phosphate buffer and incorporated into a paste of graphite powder and paraffin oil. The paste is inserted into plastic tips 3 mm in diameter and the exposed tip is polished. Silver wires are used for electrical contact. No membranes are needed to prevent fouling and the preparation of the electrodes is fast and straight forward. The response characteristics of a three-enzyme system (creatinine + creatine) were best at 650 mV, with an analytical range of 4–100 nmol l<sup>-1</sup>. With a two-enzyme system, the assay for creatine was optimal at 240 mV with a range of 4–200 pmol l<sup>-1</sup>. The actual concentration of creatinine is determined from the difference between the two readings.

Creatine and creatinine, along with *p*-aminohippuric acid and uric acid, can be determined using CE on a glass microchip with amperometric detection via screen-printed electrodes connected to an electrochemical analyzer. Creatinase, creatininase, and sarcosine oxidase are mixed with the sample, so that the actual separation is of peroxide, *p*-aminohippuric acid, and uric acid. This allows total (creatine plus creatinine) to be determined. The concentration of creatine can be determined in the absence of creatininase.

### Sarcosine

A biosensor for sarcosine can be constructed based on sarcosine oxidase entrapped in nafion, with amperometric detection using manganese dioxide-modified screen-printed electrodes. The LOD is 28 μmol l<sup>-1</sup>.

## Thin-Layer Chromatography

### Sarcosine

Sarcosine can be fluorescently labeled using 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl). This reaction facilitates quantitation of sarcosine after separation by thin-layer chromatography (TLC). TLC concentrates the species of interest into a limited area which is then scanned for fluorescence. This procedure gives extremely low detection limits (low picomoles), allowing quantitation of sarcosine even in serum samples from healthy subjects. However, ions that interfere in the derivatization step must be removed on an ion-exchange column prior to derivatization, and the sarcosine is best pre-separated from large amounts of other amino acids, which are present in sera. Thus, serum must be deproteinized using sulfosalicylic acid, then the sarcosine separated out using an amino acid analyzer connected to a

fraction collector. The sarcosine fraction is then deionized by ion-exchange chromatography before derivatization. Urine is deproteinized using ethanol before deionization and derivatization. Thus, considerable sample preparation is necessary, but the low LOD warrants this if more expensive equipment is not available.

## Liquid Column Chromatography

### Creatine and Creatinine

Chromatographic separations allow the simultaneous determination of several species of interest. Thus, there is a wide range of systems that can be used, and the method selection will be determined, to a large extent, by what other compounds need to be determined at the same time. This also dictates the detection method. The absorption of creatine is typically measured at 210 nm, while creatinine can be measured at both 210 and 230 nm and has a higher absorptivity. When amino acids or guanidino compounds are to be analyzed simultaneously with creatine and creatinine, postcolumn detection using ninhydrin can be used. Enzymatic methods can be used if coeluting compounds are a problem. HPLC methods can be automated, and are particularly useful when both creatine and creatinine need to be analyzed in urine, plasma, erythrocytes, or tissue (Figure 2).

The sample preparation varies from dilution to protein precipitation to use of a precolumn. Removal of protein is important for extending the lifetime of reversed-phase columns, although it does not affect the analysis *per se*. Urea is present in urine in high concentrations but does not absorb strongly, while uric acid and guanidinoacetate are present in relatively small amounts but absorb similarly to creatine and creatinine. These compounds can interfere with analyses of creatine and creatinine on reversed-phase columns, and their relative retention times are highly dependent on the specific makeup of the reversed-phase column being used, as well as on the eluent. Thus, a separation needs to be optimized for the particular reversed-phase column that is installed, so that these species are resolved from the species of interest.

Most eluents for the separation of creatine and creatinine on a reversed-phase column are based on a phosphate buffer (Table 2). The addition of a quaternary ammonium ion-pairing agent such as tetrabutyl ammonium sulfate increases the hold-up of interfering species to help separate them from creatine. This method is one of the most popular for simultaneous determination of creatine and creatinine. Porous graphitic columns can also be used.

## Sarcosine

Sarcosine can be analyzed by many of the standard amino acid analyzers. Typically in these, amino acids

**Figure 2** Chromatograms of plasma (A) and urine (B) from subjects supplementing with creatine. The separations were carried out on a Synergi 10 $\mu$  Hydro RP 80 250  $\times$  4.6 mm column using a 20 mmol l<sup>-1</sup> potassium phosphate buffer, pH 6.5, for the plasma and 14.7 mmol l<sup>-1</sup> potassium phosphate–2.3 mmol l<sup>-1</sup> tetrabutyl ammonium sulfate, pH 5.0, for the urine, with detection by absorption at 210 nm. For both samples, protein was precipitated out before injection using acetonitrile. The plasma and urine were diluted 5-fold and 87-fold, respectively, during sample preparation.

are separated by cation-exchange chromatography and must be derivatized for detection. There is little interference from contaminants, and minimal sample preparation is required. The most well-known derivatizing agent for amino acids is ninhydrin, which gives blue–purple derivatives (absorption measured at 570 nm) for the majority of amino acids, but for a few, including sarcosine, the derivative is purple–brown. Cation-exchange chromatography is favored because there are few matrix effects. Run times depend on the mix of amino acids and other compounds present and the particular eluent used. One common eluent system for the analysis of physiological samples is lithium citrate–chloride, which is used with a cation-exchange stationary phase regenerated with LiOH. Gradient elution is necessary for an efficient analysis. Elution generally begins at pH 2.8, and the pH and concentration of lithium citrate are increased. Buffers and columns are commercially available, with gradients customized for columns and the particular mix of ninhydrin-active species present in the samples. The initial portion of a chromatogram of a mix of amino acids including sarcosine is shown in Figure 3. Sarcosine of concentrations down to 5  $\mu$ mol l<sup>-1</sup> can be analyzed in urine or plasma. Accordingly, sarcosine does not show up in normal plasma when analyzed in this way. Although ninhydrin reagent is not very stable, there are various modifications commercially available that attempt to address this problem. For example, Trione<sup>®</sup> gives a more stable but less sensitive derivative.

Pulsed amperometric detection offers a significant advantage in that it can be used after separation of the ions by ion chromatography without derivatization, and has detection limits  $\sim$ 50 times lower than those of ninhydrin.

Precolumn derivatization of amino acids causes them to become less polar and more amenable to separation by reversed-phase HPLC. Such analyses tend to give shorter run times and higher sensitivity

**Table 2** HPLC buffers used for the analysis of creatine and creatinine

Matrix	Column	Eluent	Other compounds analyzed
Tissue, urine	Reversed phase	Potassium phosphate (14.7 mmol l <sup>-1</sup> ), tetrabutylammonium sulfate (2.3 mmol l <sup>-1</sup> ), pH 5.0	Phosphocreatine
Urine	Reversed phase	Potassium phosphate (20 mmol l <sup>-1</sup> ), pH 6.5	Uric acid, hippuric acid
Serum	Reversed phase	(Sodium phosphate (100 mmol l <sup>-1</sup> ), SDS (30 mmol l <sup>-1</sup> )):acetonitrile, 3:1, pH 2.1	Guanidino compounds
Urine	Reversed phase coated with hexadecylsulfonate	EDTA (5 mmol l <sup>-1</sup> ), phosphoric acid (15 mmol l <sup>-1</sup> ), pH 2.5	Amino acids
Serum	Porous graphite	Sodium citrate (10 mmol l <sup>-1</sup> ), sodium octanesulfonate (5 mmol l <sup>-1</sup> )	Guanidino compounds
Serum, urine	Porous graphite	Trifluoroacetic acid (0.1%), acetonitrile (3%)	

**Figure 3** Chromatogram of standard amino acids. The separation was carried out on an  $80 \times 5.5$  mm accelerated lithium cation-exchange column using 100% Pickering™ Li280 for the first 8 min and then a gradient to 23% Pickering™ Li750 over the next 14 min. Detection was by absorption at 570 nm. The amino acids in the mix are 1, phosphoserine; 2, taurine; 3, phosphoethanolamine; 4, urea; 5, aspartic acid; 6, hydroxyproline; 7, threonine; 8, serine; 9, asparagine; 10, glutamic acid; 11, glutamine; 12, sarcosine; 13,  $\alpha$ -aminoadipic acid. (Adapted from website [www.pickeringlabs.com](http://www.pickeringlabs.com) for Pickering Labs.)

than methods involving postcolumn derivatization. One common precolumn derivatizing agent for amino acids is *o*-phthaldialdehyde, but this does not react with secondary amino acids such as sarcosine. On the other hand, phenylisothiocyanate (PITC), also known as Edman reagent, reacts with both primary and secondary amino acids, forming phenylthiocarbamyl (PTC) derivatives that are analyzed at 254 nm. Pico tag columns are recommended. Unreacted PTC must be removed under vacuum or by extraction, but the whole derivatization sequence can be automated. The separation of the PTC-aa derivatives can then be carried with gradient elution using  $0.14 \text{ mol l}^{-1}$  sodium acetate, pH 6.4, with increasing concentrations of acetonitrile. Triethylamine and ethylenediaminetetraacetic acid (EDTA) are sometimes added. The exact program required will

depend on the column particulars and the components present. Sarcosine elutes between asparagine and  $\beta$ -alanine. This analysis can be used for blood and urine samples, with linear ranges from 20 to 5000 pmol.

PITC derivatives can also be detected electrochemically using an operating potential of 1.1 V. This gives lower detection limits than absorbance, and the sample preparation can be shorter and simpler.

Derivatization of sarcosine with 9-fluorenylmethyl chloroformate (FMOC) facilitates detection via fluorescence, but unfortunately the sarcosine derivatives are among the least stable of the amino acid derivatives formed this way, and the instability can lead to peak broadening.

6-Aminoquinolyl-*N*-hydrosuccinimidyl carbamate reacts quickly with amino acids in a simple procedure to give stable derivatives that can be detected by fluorescence or absorption after separation on a reversed phase at 37°C. The reagents and buffers are commercially available (AccQ-TAG).

## Capillary Electrophoresis

### Creatinine

Creatinine itself can be analyzed in 4 min using CE with a pH 6.4 phosphate buffer and detection by absorption at 235 nm. EDTA is added to prevent metal ions from interfering by binding with the creatinine. In a pH 4.05 buffer containing pyridine, tartaric acid, and 18-crown-6, cations can be analyzed along with the creatinine, using indirect photometric detection. To ensure reproducibility in CE when biological fluids are being analyzed, the capillary must be rinsed with base between runs (then water and buffer) to ensure that any proteins that may have adsorbed on the capillary wall are removed.

Addition of sodium dodecyl sulfate (SDS) in concentrations greater than that required for micelle formation ensures holdup of species that may interfere, and facilitates separation of other species in the sample that may be of interest. This is called micellar electrokinetic capillary chromatography (MECK). Apart from requiring a very small sample, an advantage of CE is that once the compound/s of interest has/have eluted, the remainder of the sample can be rapidly rinsed from the column using pressure or suction.

### Creatine and Creatinine

Baseline resolution of creatine, creatinine, and uric acid can be obtained using a pH 5.5,  $50 \text{ mmol l}^{-1}$  phosphate buffer. Best results are obtained when the

**Figure 4** Electropherogram of 100-fold dilution of urine from a subject supplementing with creatine. The separation was carried out at 17 kV with hydrostatic injection for 20 s, using a  $30 \text{ mmol l}^{-1}$  phosphate– $150 \text{ mmol l}^{-1}$  sodium dodecyl sulfate buffer, pH 6, and detection by absorbance at 214 nm. The unlabeled peak is a system peak.

sample is diluted with buffer containing 2% EDTA. MECK using  $150 \text{ mmol l}^{-1}$  SDS in a  $30 \text{ mmol l}^{-1}$  phosphate buffer, pH 6, can also be used for the analysis of creatine and creatinine (Figure 4). Migration times depend on the length of capillary and the applied voltage. The migration time for creatinine is particularly sensitive to pH, decreasing as the pH is raised. The LOD depends on the instrument used and may be as low as  $0.7 \mu\text{g ml}^{-1}$  for creatine and  $0.09 \mu\text{g ml}^{-1}$  for creatinine.

## Gas Chromatography

Creatine, creatinine, and sarcosine must all be derivatized before they can pass through a gas chromatograph.

### Creatine and Creatinine

Unfortunately, in most cases creatine and creatinine form the same derivatives, and so the two must be separated before derivatization. This can be accomplished using a weak cation-exchange column. Creatine elutes in water while creatinine elutes in  $1 \text{ mol l}^{-1}$  ammonia. Suitable derivatizing agents are shown in Table 3.

### Sarcosine

An <sup>TM</sup>EZfaast kit facilitates the cleanup and derivatization of mixtures of primary and secondary amino acids. The derivatives can then be analyzed by GC–FID or GC–MS. The latter method gives lower LODs.

Other derivatizing agents that can be used are shown in Table 4.

**Table 3** Derivatives of creatinine for analysis by GC–MS

Derivative	Reagent(s)
(2-Hydroxy, 2-methyl)ethylcreatinine di(trifluoroacetate)	1,2-Epoxypropane then trifluoroacetic acid
Ethyl ester of <i>N</i> -(4,6-dimethyl-2-pyrimidinyl)- <i>N</i> -methylglycine	2,4-Pentanedione, ethanol, acetic acid
Trimethylsilylcreatinine	<i>N</i> -Methyl- <i>N</i> -trimethylsilyltrifluoroacetic amide (MSTFA)
<i>O</i> -Trifluoroacetylcreatinine	Trifluoroacetic anhydride

**Table 4** Derivatives of sarcosine for analysis by GC–MS

Derivative	Reagent(s)
<i>N</i> ( <i>O</i> )- <i>tert</i> -Butyldimethylsilyl sarcosine	<i>N</i> -Methyl- <i>N</i> -( <i>tert</i> -butyldimethylsilyl)trifluoroacetamide and <i>N,N</i> -dimethylformamide
<i>N</i> -Pentafluoropropionyl hexafluoroisopropyl ester	Pentafluoropropionic anhydride and hexafluoroisopropanol (2:1)
Mono- and di-trimethylsilylsarcosine	<i>N,O</i> -bis(trimethylsilyl) trifluoroacetamide (BSTFA)

## Mass Spectrometry

GC–MS gives very low detection limits and positively identifies the presence of a species of interest. Internal standards are often used, typically an isotopically labeled species.

### Creatinine

Isotope dilution analyses give very accurate results but are not suitable for routine analysis. Standards can be labeled with  $^{15}\text{N}$ , deuterium,  $^{13}\text{C}$ , or a combination. Several isotope dilution-GC–MS methods for creatinine have been proposed as reference methods.

LC–APCI–MS can also be used to determine creatine and creatinine. However, the sample must first be cleaned up by ion-exchange chromatography, and the LOD is not as low as for some simpler methods. Urinary creatine, creatinine, and guanidinoacetate can be determined by HPLC–MS using 2% acetonitrile in  $100 \text{ mmol l}^{-1}$  ammonium acetate as eluent.

### Sarcosine

Sarcosine can be determined along with other amino acids by GC–MS after derivatization. Using single-ion monitoring, LODs of 50 fmol or lower can be obtained with sample sizes of a few hundred microliters. Derivatization by methylation with diazomethane is not suitable as glycine could be methylated to sarcosine, and produce a positive interference.

## Nuclear Magnetic Resonance

### Creatine, Creatinine, and Sarcosine

Proton NMR can be used to examine the composition of urine.

Using a 500 MHz instrument and solvent ( $\text{H}_2\text{O}$ ) suppression, the spectra are collected using 0.5 ml urine with  $50\ \mu\text{l}\ 20\ \text{mol l}^{-1}$  sodium 2,2,3,3-(trimethylsilyl)tetradeuteriopropionate in  $\text{D}_2\text{O}$ . Peaks are assigned by comparison to standards and by use of various pulse sequences. Peaks can be seen for creatine, creatinine, and sarcosine. Creatine is generally elevated in the urine of infants. Sarcosine concentrations in the urine of normal healthy patients are too low to be seen by this method.

$^{13}\text{C}$  NMR spectroscopy can be used to follow the metabolism of  $[2-^{13}\text{C}]$ creatine in tissue culture.

## Inborn Errors of Metabolism

**D H Chace**, Pediatrix Screening, Bridgeville, PA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

There are ~1300 different types of metabolic diseases that have been found in children. Individually, these diseases are quite rare; combined, they are not. Statistics from a subset of inherited disorders of

metabolism (55 disorders analyzed by newborn screening) reveal a combined incidence of more than 1 in 1000 in a study population of 1.5 million. A vast array of methods has been used to measure diagnostic metabolites of these disorders in many biological fluids from newborns, infants, children, and adults. Many of these diseases share common symptoms including retarded growth and mental development, failure to thrive, abnormal electrolytes, etc., and produce severe disabilities, coma, or death if not

treated early or appropriately. Historically, clinical methods were designed to detect disease in affected children with symptoms. The analysis performed was based on a suspected diagnosis and often was a single analyte test with a few notable exceptions. Recently, newer technology has enabled multianalyte testing for a variety of disorders in symptom-free neonates. This multiplex approach is cost-effective for the rare disorders that generally characterize inborn errors of metabolism (IEM). The primary focus of this article will be the accurate multianalyte techniques (e.g., mass spectrometry) rapidly replacing outdated older technology.

## Metabolites: Products and Substrates of Enzymes

An inborn error of metabolism presumes that a protein that comprises an enzyme or enzyme complex is abnormal. The kinetics/rates of metabolism of this altered protein/enzyme may be severely impaired or only mildly affected depending on how the protein is altered. Genetic mutations that directly alter its active site or interaction with co-factors would have deleterious consequences to enzyme activity as compared to minor alterations in protein structure or in less critical areas of protein structure and function. From an analytical perspective, alterations of these enzymes directly affect the concentration of their precursors and products. It might be deduced that enzymes with little activity would produce the most dramatic changes in the concentrations of metabolites. However, in these cases, the metabolites produced in high or low concentration have minimal effect on overall metabolism and may even have no consequence unless stressed by environmental or dietary circumstance. What is important to note is the simple fact that the concentration of metabolites is more closely correlated with a disease state than are abnormal enzymes and the genes that code them. The burden of diagnosing and confirming a disease requires the analysis of metabolites. The absolute concentration of a metabolite and its relative concentration to other metabolites will determine the likelihood or certainty of a metabolic disorder. The preliminary analytical results will subsequently influence the manner of further metabolic investigation and confirmation of the disease leading to ultimately, a final diagnosis.

A schematic illustration of the relationships of metabolites in various metabolic disorders is presented in Figure 1. In a simple metabolic system (Figure 1, panel i), metabolite A is converted to metabolite B by enzyme X. In presumably healthy states, the concentrations of A and B will be within a

**Figure 1** Illustrations showing substrates and products of enzymatic pathways involved in inborn errors of metabolism. Three panels (i, ii, iii) contain both normal and abnormal substrate (A) metabolism to product (B). Larger upper case bold fonts indicate higher concentrations than either normal (upper case fonts) or low (lower case, smaller fonts) concentrations. Panel (i) represents a simple scenario of metabolism of substrate A to B with alternate minor pathway c. Panel (ii) represents a scenario of substrate C metabolism to product A, which is a substrate for the enzyme X forming product B. Panel (iii) represents a scenario of substrates A, C, and E metabolized to products B, D, and F by the same enzyme X.

range considered 'normal'. The metabolite A may have alternative, minor metabolic pathways. This pathway involves enzyme Y that converts metabolite A to metabolite C. In a disease state where the activity of enzyme X is impaired, the concentration of A (the substrate) is increased, while the concentration of B (the product) is decreased. With a substantially elevated concentration of A, kinetics dictates that the alternate pathway will be utilized to a significant degree, producing increased concentrations of C. An example of this system may be observed in phenylketonuria where a deficiency of the enzyme phenylalanine hydroxylase produces a substantially increased concentration of phenylalanine while not producing the product tyrosine. From an analytical perspective, the analysis of a body fluid, blood or plasma, for example, would show an increased concentration of Phe and a possible decrease in Tyr. Further, very high levels of Phe are metabolized by alternative enzyme pathways to produce phenylpyruvic and phenylacetic acids. These metabolites are toxic in high concentration and produce brain damage.

A second metabolic system similar to the first is shown in **Figure 1**, panel ii. In this schematic, the emphasis is a metabolite one or two steps proximal to the primary enzyme deficiency. For example, in normal individuals, metabolite C is converted by enzyme Y to metabolite A, which is subsequently converted by enzyme X to metabolite B. As described above, in individuals with an inherited deficiency of enzyme X, metabolite A accumulates. In this particular scenario, compounds that are converted to metabolite A, namely metabolite C, will increase as enzyme Y is inhibited by basic kinetics. An example of this enzyme system is homocystinuria. In this disorder, the metabolism of homocysteine to cystathionine by cystathionine  $\beta$ -synthase is blocked. An increase in homocysteine causes an accumulation of S-adenosyl homocysteine and S-adenosyl methionine. Due to an increase in these metabolites, the metabolism of methionine to S-adenosyl methionine by methionine adenosyl transferase is decreased. Hence, methionine increases in the blood of individuals with homocystinuria. Note that in this example there were two enzymatic steps before the metabolism of homocysteine.

In the final example of metabolic disorders, **Figure 1**, panel iii, more than one metabolite are metabolized by a single enzyme system. In this instance, enzyme X converts three different compounds to three different substrates, A to B, C to D, and E to F. If a deficient enzyme X is present, all three substrates, A, C and E, are expected to increase while substrates B, D, and F are expected to decrease. An excellent

example of this scenario is medium chain acyl CoA dehydrogenase (MCAD) deficiency and their beta-oxidation disorders. The enzyme, MCAD, is specific for medium chain acyl CoAs. These include octanoyl CoA, hexanoyl CoA, and decanoyl CoA, among others. In MCAD deficiency, it would be expected that all three species would be elevated, and they are indeed.

These three schemes of metabolism offer a unique perspective for discussing the analysis of metabolites in clinical chemistry labs. Traditionally, many laboratories have utilized the one analyte, one disease approach to testing. Hence, metabolite A in each of the scenarios would be a single measurement made in a laboratory, often by a relatively nonspecific test such as an immunoassay or fluorometric analysis. There are often numerous circumstances that can produce an elevation of a particular metabolite in addition to an enzyme deficiency produced by a metabolic disease. The result is a false positive. Measurement of more than one metabolite that is affected by a particular enzyme, Phe and Tyr as in the case of phenylketonuria (PKU), reduces the likelihood of a false positive as these amino acids are 'linked' metabolically. The case is similar in scenarios 2 and 3 where the pattern of metabolites may indicate one or more disorders that share common metabolic pathways. One final point regards scenario 2. Measurements of metabolites 2 or more steps away from the primary metabolic block, theoretically and in practice, are somewhat less reliable indicators of disease than the primary substrate. Often, however, no alternative is presented due to the primary substrate being chemically unstable or difficult to measure analytically. Generally, these metabolites are easier to detect in older infants as they accumulate over time.

## The Metabolic Profile

Unlike many routine clinical chemistry tests, clinical analyses of IEM almost always involve a multiple metabolite analysis. The results form the basis of a metabolic profile in which both individual concentrations of metabolites and their relationship to each other can be viewed either in tabular form or in a graphical display. Perhaps the most comprehensive and historically significant test in IEM studies is gas chromatography/mass spectrometry (GC/MS) of a derivatized extract of urine. **Figure 2** is a chromatogram from an infant with propionic acidemia, an organic acid disorder of leucine metabolism. Hundreds of volatile compounds of carbohydrate, amino acid, fatty acid, and nucleic acid metabolism are separated in 40 min using capillary GC. Addition

**Figure 2** Capillary gas chromatogram of a derivatized urine extract from a patient with propionic acidemia. The mass spectrum of a peak at 28.7 min is shown in the inset and identified as propionylglycine, one of the metabolic indicators for propionic acidemia.

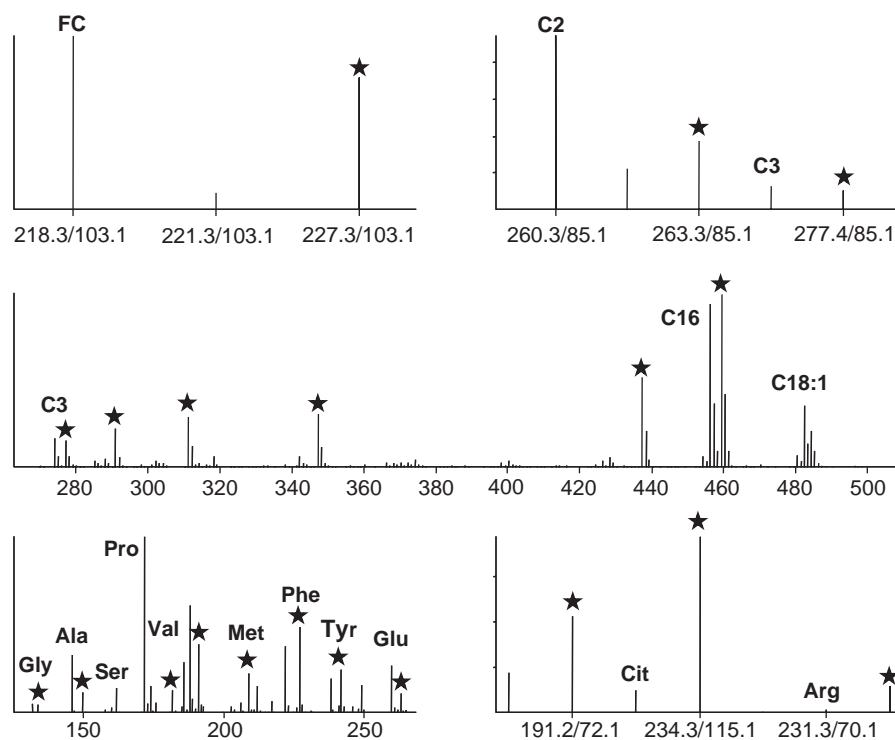

of a mass spectrometer as a detector improves identification of peaks at a particular retention time since separation of each component is often incomplete. An example of the mass spectrum of propionylglycine, a metabolite associated with propionic acidemia, is shown in the inset of **Figure 2**. Since other diseases can be detected in an organic acid analysis, it is perhaps still the most powerful tool in the diagnosis of metabolic disorders.

More recently, a complementary approach to clinical analysis of IEM is tandem mass spectrometry (MS/MS). This method is currently used to analyze numerous amino acids and acylcarnitines in a single analysis. One advantage of MS/MS (when compared to GC/MS) is that it does not require chromatography and hence lends itself to high volume clinical analysis of hundreds of samples per day. Another advantage of MS/MS is that it is a soft ionization, liquid chromatographic system that enables the analysis of ionic and polar compounds without extensive derivatization. An example of a typical MS/MS analysis of amino acids and acylcarnitines extracted from a dried newborn blood spot is shown in **Figure 3**. More than 65 separate compounds are detected in a single analysis. The concentrations of individual metabolites and, in some cases, their relationship to each other, are used to presumptively diagnose more than 35 disorders of amino acid, organic acid, and fatty acid metabolisms. Similar methods have been used to analyze blood, plasma, and urine from infants suspected of a metabolic disorder as well as to analyze postmortem specimens collected at autopsy from infants who have died of unknown cause.

Both GC/MS and MS/MS serve as confirmatory tests for each other. Modern clinical laboratories specializing in diagnosis of IEM utilize both techniques considering the quantity of information obtained using GC/MS and MS/MS. It is important to note that there are other methods in addition to GC/MS and MS/MS that are important in the diagnosis of disease and its confirmation. As the medical community places increased emphasis on reducing or controlling cost and clinical chemists are required to improve laboratory efficiency and become more regionalized and specialized, techniques such as GC/MS and MS/MS will remain the primary tools of choice for the foreseeable future.

## Specimen Characteristics

The type of biological specimen and form of collection is important in IEM. Although this statement appears obvious, there are a large number of considerations and implications of their use. Urine specimens are characterized primarily by hydrophilic metabolites that are often extensively modified from the original endogenous metabolite that accumulated in a metabolic disorder. As discussed previously, which compounds are present in the form of a metabolic profile is important in diagnosing a disorder but determination of concentration requires many assumptions. Because higher or lower urinary output affects the dilution of various metabolites, an indication is required to standardize urine concentration. Hence, creatinine is used as an indicator of urinary

**Figure 3** Tandem mass spectra from a typical analysis of the derivatized extract of a newborn blood spot. The five panels represent five types of analyses in a single 2 min run. These include (left to right, top to bottom), an analysis of free carnitine, short chain acylcarnitines, acylcarnitine profile, amino acid profile, basic amino acids. The stars represents internal standards for quantification.

output and most concentrations are reported as a concentration per milligram of creatinine. Few clinical labs analyze liquid blood directly for metabolites. Whole blood is either separated into plasma or serum and red cells. Traditionally, most clinical analysis is performed from plasma. Metabolites in plasma are often quite different from metabolites in urine, being of course less extensively modified. Plasma contains both hydrophilic and many lipophilic compounds with the latter requiring association with protein compounds for solubility. Blood can also be applied to an adsorbent filter paper specifically designed to have specific plasma volume equivalence per area of the sample at a specific hematocrit. This sample used in clinical labs, is the specimen of choice in newborn screening labs, and is increasingly used in metabolic specialty labs. Since blood can be applied to filter paper without precise application (a simple drop of blood from a heel stick), it is convenient from the screening perspective. However, it is quantitatively poorer since an individual's hematocrit and methods of application vary considerably. Nevertheless, its use is expanding with techniques such as MS/MS where emphasis is placed on a semiquantitative metabolic profile and relative ratios of metabolites to each other.

## Patient Characteristics

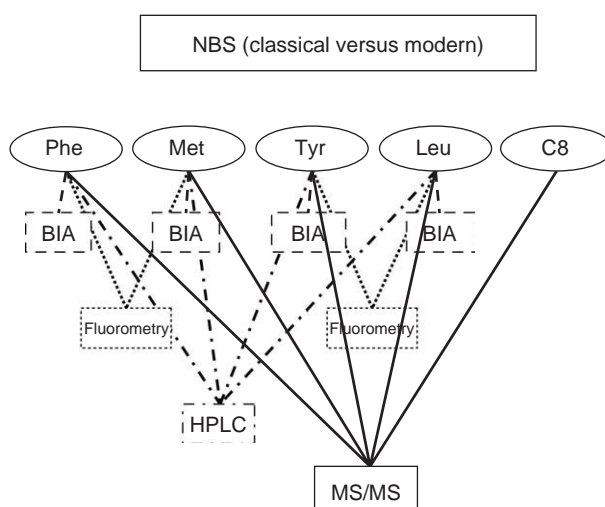

The age of the patient when a sample was collected is extremely important in a clinical analysis of IEM. Illustrations of this are plentiful in newborn screening where the first 7 days of life demonstrate many metabolic changes, the most important of which is at 'time zero' when the infant can no longer rely on maternal metabolism and nutrition. Generally, very early collection of blood, plasma, or urine specimens may be unreliable especially for diseases that are affected mostly by diet. The best example is phenylalanine and detection of PKU. The concentration of phenylalanine increases with time in affected individuals. This rate of accumulation depends upon many factors, but the most important being the degree of loss of enzymatic activity of phenylalanine hydroxylase and the influx of substrate, phenylalanine, from dietary protein sources. Historically, older, less accurate methods such as bacterial inhibition assays required a minimum of 48–72 h before an elevated Phe could be reliably used to detect PKU without substantial false negative and false positive rates. With newer technology as shown with MS/MS this can be reduced to 24 h without an increase in the false negative rate and with an important significant

decrease in the false positive rate. In fact, PKU and other amino acidopathies can be detected even earlier when necessary and as a safeguard to early discharge of patients. In other disorders such as  $\beta$ -oxidation defects that are analyzed via acylcarnitines, early detection (1–3 days) appears to be more reliable than an analysis of dried blood specimens more than 7 days of age due to substantially decreased concentration of carnitine and acylcarnitines. On the other hand, the reliability of organic acid analysis of this same disease improves with age. Other important characteristics are whether a patient is symptomatic, presymptomatic, deceased, prenatal, undergoing dietary treatment, supplementation, etc. Each has a different metabolic profile characteristic and is important in the analysis of a disease state and its detection.

## Analytical Characteristics

Choice of analytical methods in clinical chemistry is perhaps one of the most important decisions a clinical chemistry/laboratory director can make. Choosing a method requires the following considerations: types of specimens received, numbers of specimens per day, turnaround time, accuracy and specificity required, cost-effectiveness, cost-benefit ratio, expertise required, etc. Meaningfulness and interpretation of results are directly determined by which method is utilized. This is illustrated in two examples, methods used to diagnose PKU and MCAD deficiency. A flow chart (Figure 4) is utilized to illustrate the choices of methods for analyzing a modern panel of metabolites used in newborn screening showing older technology such as bacterial inhibition assay (BIA) and modern technology such as MS/MS.

In the earliest days of clinical chemistry, many methods relied on the biological responses of organisms to a particular stimulus. Robert Guthrie, in the early 1960s, developed a bacterial culture that would only grow in the presence of phenylalanine and would reverse the inhibition of a compound that inhibits its growth. This assay, known as BIA, was the stimulus for newborn screening of metabolic disorders. At the time, this method was inexpensive, high-volume capable, and easily implemented in public health laboratories. Further, samples could be collected on a piece of cotton-based filter paper from presymptomatic patients a few days after birth and mailed to a laboratory for analysis. The only other alternative at the time was a more expensive, high-performance liquid chromatography (HPLC) based analysis using liquid plasma from symptomatic patients. Problems with screening, however, became

**Figure 4** Flowchart showing classical and modern approaches to newborn screening. The top panel represents the desired analyte with bottom panels representing analytical approaches. The earliest technology, BIA, requires one assay per metabolite. A more recent classical approach is fluorometry, which may allow for two simultaneous analyses with one instrument. Still more recently is HPLC, which allows for an analysis of compounds in a panel with shared characteristics, e.g., amino acids. Finally, the most recent approach is MS/MS, which allows profile analysis of more than one compound type such as amino acids and acylcarnitines.

apparent by relatively high false results. Newer methods such as fluorometric assays later became integrated into laboratories. These methods improved reproducibility, no longer were biologically based assays dependent upon the response of an organism, and were still inexpensive. However, the false results were still high because like many immunoassays, the specificity of the fluorescent complexes with phenylalanine are fairly nonspecific for similar compounds. More recently, methods such as MS/MS overcame these limitations while presenting few shortcomings. First, MS/MS can be used in a highly selective analysis for Phe, it is versatile in that it can be used for both liquid and dried specimens, it is as accurate as either BIA or fluorometry (theoretically more accurate in liquid but not in filter paper specimens), it is inexpensive (for high-volume laboratories using MS/MS in conjunction with other assays), reliable, has a lower false positive rate that is at least 10–100 times better than other methods, and can improve diagnostic accuracy by measuring tyrosine in addition to phenylalanine (the ratio of Phe/Tyr is important in distinguishing a spurious elevation of Phe due to double spotting or hyperalimentation with amino acids). A limitation of the method is that it requires experience and expertise that is improving with progress in the ease of use of the

technology and increasing numbers of experts that are accessible. Further, due to its reliability and reduced false positive results, follow-up analysis and confirmation is more rapid, resulting in earlier treatment and medical care.

Most recently, a better understanding of the intermediary metabolism of fats and related disorders was realized primarily because analytical methodology improved to investigate the fundamental biochemistry. Interestingly, this same technology that led to improved understanding of  $\beta$ -oxidation resulted in an adaptation for the diagnosis of disorders of fat metabolism. Analysis of acylcarnitines was historically difficult using HPLC or GC due to the fact that these compounds are unusual in that they have both negative and positive side chains similar to amino acids in solution but with a fundamental difference in the esters they form with fatty acids on their aliphatic alcohol side chain. Depending upon the length of these side chains, compounds vary widely in their hydrophobicity. Hence, HPLC methods are excellent for measuring short chain acylcarnitines but poor for long chains. Radioimmunoassays and turbidimetric assays can only measure free carnitine. MS/MS, however, can measure both free and acylcarnitines providing both a measure of total carnitine and its fractions as well as individual metabolites. Measurement of individual metabolites in a profile is important in diagnosing numerous IEM. In fact, at this time, no other method can replace MS/MS as the primary analysis of numerous IEM in blood.

In both of these examples, PKU and fatty acid oxidation disorders, the methods utilized at this time are characterized by their comprehensiveness, cost-benefit ratios, and their ability to be used as part of a diagnosis of a particular disorder. In fact, these methods demonstrate that the future of clinical chemistry is multianalyte analysis that enables low cost even with relatively expensive instrumentation. Multianalyte analysis is not new to clinical chemists as the chemistry analyzers in hospitals and labs are used to analyze several dozens of compounds. A close look at these assays, however, will demonstrate that they are not true multiplexed analyses but rather a large robotic system performing 24 individual assays with 24 different chemistries and standards. MS/MS enables a single analysis, a single chemistry, and many results.

## Diagnostic Characteristics

It is important to emphasize that the purpose of a clinical analysis is to provide information regarding the metabolic status of a patient and whether a

particular analysis reflects a normal chemistry or that which deviates significantly from normal. To do this well, an analysis must fit the obvious criteria of high precision and accuracy resulting in few false results. There is, however, a challenge facing clinical chemists to provide more than a quantitative result and to provide information as to the probable diagnosis thus assisting a physician in making this determination. For example, consider analysis of a blood specimen for phenylalanine that reveals a concentration of  $240 \mu\text{mol l}^{-1}$  ( $4 \text{ mg dl}^{-1}$ ). From the physician's perspective, whether this patient has PKU or not is the question. A screening method that reports a concentration of 240 requires further testing and repeat analysis causing delay in treatment or unnecessary anxiety if subsequently normal. Consider a method that measures other amino acids, including tyrosine. Methods that provide both results enable a better estimation of whether or not this patient likely suffers from PKU. An elevated ratio of Phe/Tyr together with an elevated phenylalanine increases the probability of a truly positive case of PKU. Furthermore, a method that measures additional amino acids may suggest something different. For example, consider that leucine, methionine, and alanine were also elevated. Does this suggest a premature infant or perhaps an infant whose hyperalimentation has low concentrations of tyrosine (a possibility considering that some supplements have low concentrations of tyrosine due to its solubility characteristics)? Methods that provide more information improve the diagnostic characteristics of a test and help to determine whether repeat analysis is urgent, necessary, or should wait until medications are discontinued. As methods assist physicians in making a metabolic diagnosis, physicians can alter their response to analytical results.

It is also important to consider in any debate about whether a metabolic analysis is a diagnosis in and of itself: can a metabolic disease be diagnosed in an asymptomatic infant in the case of MCAD deficiency? The answer is no. If that is the case, is the analysis by MS the only method that can be used to diagnose a patient with MCAD deficiency in the newborn period? The answer is unclear in that no diagnosis would be made without an analysis but this analysis alone will not definitively diagnose MCAD deficiency without confirmatory testing such as DNA analysis, urine organic acids, or other studies. As is the case in forensic science, clinical science requires more evidence of a disease than a single test no matter how low the false positive or false negative rates are. Nevertheless, methods that improve the likelihood of an accurate diagnosis early enable a physician to spend more time treating a patient when the

maximum benefit is realized, before symptoms are present.

## Rare Disorders

Perhaps the single most important factor affecting clinical analysis in IEM is that these disorders are rare, relatively infrequent. This simple fact affects the who, what, why, and where for a clinical analysis of a metabolic disorder. Consider a disease that affects 1 in 15 000 individuals. The total number of patients expected to be affected per year in the US is ~250 based on the birth rate of 4 million. To what extent do we apply capital resources to developing methods to detect these disorders? What methods should be used? Is there benefit to early intervention and diagnosis? What is the cost of analysis? Are there metabolic experts knowledgeable in the diagnosis and treatment? Is the analysis accessible? Consider that a metabolic disease with a frequency of 1 in 15 000 is considered relatively frequent in the world of IEM as most diseases have frequency of 1 in 50 000 or less. IEM are therefore quite different than diseases affected by environmental influences or the aging process. A clinical analysis of inborn errors ideally would include methods that analyze more than one disease in a single test, perform many different analyses for multiple disorders in larger specialized labs rather than in individual hospitals, or biomedical labs that perform routine blood chemistries, and develop a network of metabolic experts to diagnose and treat these patients. Simply stated, consider a series of rare disorders screened with one technology as if they were one disease state, i.e., disorders of fat metabolism. This is best illustrated by MS/MS, which has changed the face of newborn screening, a change not realized since Dr. Guthrie first established the blood spot analysis of PKU. For example, PKU has a frequency of 1 in 12 000 whereas MCAD has a frequency of 1 in 14 000. Combining all the frequencies of disorders that should be screened regardless of individual frequencies without additional work produces a rate of more than 1 in 3000. Viewing metabolic diseases as a 'single group of disorders' provides the necessary financial and medical resources to support the clinical analysis of IEM.

# COAL AND COKE

**J A Pajares and M A Díez**, Instituto Nacional del Carbón (INCAR), Consejo Superior de Investigaciones Científicas, Oviedo, Spain

## Introduction

Coal may be regarded as a combustible sedimentary rock. Whereas the majority of rocks are mostly inorganically derived, coal consists predominantly of organic matter, largely derived from a variety of plant remains (higher plants, ferns, fungi, algae) and different tissues (leaves, stalks, woody trunks, bark, pollen, spores, sclerotia, resins, etc.) with associated mineral constituents.

In the first stage of the evolution of coal from vegetable matter – diagenesis – changes in composition were due to biochemical processes, involving the degradation in a humid environment of the cellular structures and of the organic complex of the vegetable matter by activity of fungi and bacteria. Further alteration is a geochemical process – catagenesis – combination of the effects of pressure (due to overlying sediments) and mainly of heat (subsidence brings a rise of temperature) over a prolonged period. Evolution in chemical composition results in losses of water and gases ( $\text{CH}_4$ ,  $\text{CO}_2$ ) and, consequently, a reduction of hydrogen and oxygen contents, a decrease in volatile matter content, and a progressive enrichment in carbon content. Along these processes – coalification (Figure 1) – the original plant remains were progressively altered to

peat, lignite, subbituminous coal, bituminous coal, semianthracite, and anthracite.

The stage of coal alteration gives rise to the concept of rank – the greater the alteration, the higher the rank of the coal. Thus, lignite and subbituminous are described as low-rank coals, bituminous are termed medium-rank coals, whilst semianthracite and anthracite are termed high-rank coals. Coals of higher rank than lignites are often referred to as hard coals.

In addition to rank, two other parameters are important in coal classification, type and grade. Type of coal refers to the amount and sort of organic constituents called ‘macerals’ (see below), whereas grade refers to the relative purity or the amounts of ash-forming minerals found in coal.

Coal mines are spread over 100 countries. Mining may be surface or underground depending on whether the coal seam is exposed or at high depth. Known coal reserves are estimated over  $10^{13}$  tons and, at current production levels, workable seams are estimated to cover consumption beyond 225 years. About 90% of these reserves are in the Northern Hemisphere, with three countries – USA, China, and the former Soviet Union – accounting for about two-thirds of the total.

World hard coal production reached 3837 million tons in 2002, with a 50% rise in the last 25 years. Production of lignites was 897 Mt, Germany being the largest producer (~20% of the total). Data on the major producer countries are given in Table 1. Production of hard coal is increasing in Australia, South Africa, India, and in some new countries in the hard coal market, such as Indonesia, Colombia, and Venezuela. On the other hand, production is generally decreasing in those countries belonging to the European Union.

**Figure 1** Scheme of the formation of coal in terms of rank (coalification series).

**Table 1** Coal production. Major producers of hard coal (2002)

Country	Production (Mt)
China	1326
USA	917
India	334
Australia	276
South Africa	223
Russia	164
Poland	103
Indonesia	101
Ukraine	83
Kazakhstan	71

Data from World Coal Institute.

**Table 2** International hard coal trade. Major coal exporters (2002)

Country	Exportation (Mt)
Australia	198
China	86
Indonesia	73
South Africa	69
Russia	45
USA	36
Colombia	34
Canada	27
Poland	23

Data from World Coal Institute.

The recession in coal mining in Europe and the need of Southeast Asian countries for coal as energy source has determined a marked increase of the international coal trade from some producer countries to those two neuralgic points. Data for 2002 are given in **Table 2**. Total trade reached 625 Mt. USA's contribution is decreasing because coal companies are not interested due to weak coal market conditions. Australia is the first coal exporter, having actually a market share of 25% of the European coking coal market and practically 100% of the coking coal market in Japan.

Coal takes care of 25% of the world's primary energy, with forecasts for the next 15–20 years of 2% per year energy growth and a little higher growth, 2.2%, for coal production. Productivity depends on the grade of mechanization and other factors. Actually, the average mining costs in the USA are in the order of \$5–6 ton<sup>-1</sup> in surface and \$14–20 ton<sup>-1</sup> in underground mining. Productivity ranges from country to country from less than 1000 ton per person a year to 220 tons per person and for a shift of 8 h in the Powder River Basin surface mining. The price of a ton of coking coal (~\$50) is larger than the price of steam coal (\$40) in a global market of ~US\$125 billions.

Combustion, carbonization, gasification, and liquefaction are considered the four grand processes in the utilization of coal. In general terms, 92% of the coal production is used as fuel and ~8% is carbonized to produce metallurgical coke. Coal combustion is carried out in thermal utilities for electricity production, co-generation plants, and cement factories. Coal combines with oxygen from the air giving carbon dioxide and heat:

Conversion to electric energy reaches efficiencies from 15% to 20% for old installations to >45% for

new plants with pressurized fluid bed reactors or supercritical condition boilers. About 40% of the world's electricity production is based on coal; in countries such as China, Australia, or South Africa, more than 80% of electricity needs are met with using coal. Indeed, electricity from coal, with all restrictions derived from the Kyoto protocol, still meets 52% of electricity demands in countries such as Germany and USA.

The process of iron production in blast furnaces is the major application of metallurgical coke (about 90% of the coke produced worldwide). The whole coal consumption in the iron-making industry comes from two routes. On the one hand, coking coals are needed to produce metallurgical coke with strict quality specifications to feed the blast furnace. Currently, ~700–800 kg of coke are produced from 1 ton of coal, so to produce 340 Mt of coke for the blast furnace, ~450 Mt of coking coal needs to be carbonized in 250 coking plants around the world. Excellent coking coals are mined in Australia, Canada, China, USA, and Poland. On the other hand, coal is also consumed by the steel industry in blast furnaces operating with pulverized coal injection (PCI). As an example, blast furnaces with PCI require 700 kg of coal for each ton of hot metal produced, 525–600 kg of coking coals to make 350–400 kg of coke, and 100–200 kg of cheaper coal to be injected via the tuyeres.

Among the nonsteel blast furnace applications, foundry iron is the second most important application of coke produced from coking coals. An estimation of the global production is between 50 and 55 Mt per year. Coke for electrometallurgical reduction processes represents a minor consumption. In the nonsteel applications, coke is used as a reducing agent or as an energy source in industrial applications such as ferroalloys, lead–zinc smelting, silicon carbide production, and stone wool.

## Preparation

In most coal-producing and consuming countries, national standard methods are available for preparation, sampling, and analysis of coal. Through the International Organization for Standardization (ISO) considerable progress has been made toward the development of internationally acceptable procedures. Most of the ISO procedures are based on standard methods formulated by National Organizations such as the American Society for Testing Materials (ASTM), the British Standards Institution (BSI), the German Normenausschuss (DIN), and Poland's Standards Committee (PN). In this article,

specific ISO and ASTM standard procedures are referred to.

In surface mining, the overlying rock (overburden) is removed and the coal extracted. According to geological and topographical conditions, different methods (opencast, open pitch, etc.) and equipment (shovels, draglines) are used. Conventional room and pillar mining has been largely replaced by continuous methods – continuous miner and long-wall systems – in underground extraction. But, in all cases, the coal extracted by any of these techniques will have suffered contamination with incombustible rock and water.

Mineral matter is incorporated to the coal seam from different origins along the coalification period

1. as trace elements from decomposition of vegetable matter;
2. as detrital minerals from fluvial contribution during the diagenesis evolution;
3. as mineral inclusions (calcite, pyrite, kaolinite, etc.) from the neighboring rocks during tectonic folding in the subsidence period; and
4. through the mechanical contamination cited above.

All the contributions determine percentages in the inorganic matter of coal that range from less than 2 mass% (some Indonesian ultraclean bituminous coals) to more than 50 mass% in some run-of-mine material.

Depending on the intended end-use of coal, removal of this extraneous inorganic matter, to a greater or lesser extent, is necessary. Diminishing the ash and sulfur content is important for a better handling of boilers and to fight air pollution. Limits in emissions to concentrations of nitrogen and some minor elements, such as mercury, are already established or near to be established. Coking coal is required with 10 mass% ash and 1 mass% sulfur contents as upper limits. To achieve the derived end-products the run-of-mine mineral is treated in coal preparation plants.

In a preliminary treatment, the run-of-mine material is crushed to a size of <150 mm. This raw material, between 2 and 150 mm (named coarse), is treated through cleaning devices that use the difference in solid density between coal and mineral matter. Some heavy media – organic liquids, inorganic salts, and suspended solid particles of magnetite – are used to produce different specific gravities. Smaller mineral fractions (2–100 mm, small, and 0.5–1 mm, fines) are separated through hydraulic separation machines (jigs) based on the rate of sedimentation. Finally, solids <0.5 mm (ultrafine) are treated in

flotation cells. The cost is correspondingly higher for a higher proportion of fines. Dewatering is done by means of centrifuges and the different products from the preparation plant are stored separately in silos. By dosing and blending, ash and moisture contents can be adjusted automatically according to the market.

Although cleaning was driven by quality requirements of metallurgical coal, pollution control has increased the need to improve the quality of steam coal. Actually, the number of coal preparation plants is ~2200 and they treat ~1800 Mt of run-of-mine material with a 73% recovery rate. Although the average plant capacity is 190 tons h<sup>-1</sup> biased by the small capacity Chinese units (>1500 tons), an average of 1000 tons h<sup>-1</sup>, are more in line with those established in Western countries. In the USA, there are ~100 plants with a capacity of more than 900 tons h<sup>-1</sup>, the largest in the world being Grooteegelunk, Republic of South Africa (8200 tons h<sup>-1</sup>).

## Sampling

Coal sampling may be defined as the extraction of a small amount of material from a larger bulk of coal such that the sample extracted is representative, as far as possible, for all analytes of interest. Sample preparation, which may involve drying, crushing, and subsampling, is an integral part of the sampling process.

The compositional variability of the material is such that coal sampling becomes a complex and difficult operation. The various standardization organizations around the world have all issued detailed documents that specify the conditions and methods necessary to obtain representative coal samples for analysis.

The process of sampling, which may vary from a 2 ton domestic consignment to a 165 000 ton export shipment, involves obtaining a number of increments (spot samples, the product of a single action of the sampling device) that are combined to form one or several gross samples. Gross samples may then be crushed and subsampled (subdivided) to provide the analytical sample.

Coal samples may be obtained by either manual or mechanical sampling devices, the latter being more appropriate where large tonnages are experienced (e.g., at coal shipment terminals with throughputs up to 10 000 tons h<sup>-1</sup>) and where continuous operations or operator safety dictate their use.

Standard methods for obtaining coal samples specify minimum numbers of increments required to form a gross sample, based on a consignment

(unit) mass of 1000 tons. For consignments of greater mass, the number of increments may be increased to provide a larger gross sample, or the consignment may be considered as several subconsignments, each of 1000 tons. For each of them, a separate gross sample is collected, to be individually processed and analyzed.

As well as the mass of the consignment, the required minimum number of increments is influenced by

- the quality of coal – washed or cleaned coals are more homogeneous and therefore require fewer increments than blended or untreated coals and
- the sampling process to be used – stopped-belt or falling-stream sampling requires fewer increments to attain the required precision than sampling from barges or stockpiles.

Sample preparation involves a series of operations such as reduction of size, homogenization, and reduction of the mass of the gross sample to that suitable for analysis. For the determination of size distribution, no sample preparation other than air drying and reducing the mass of the gross sample is undertaken. For other analysis, the extent of sample preparation is dictated by the intended analysis. For example, when testing for Hardgrove Grindability Index (ISO 5074, ASTM D409 or equivalent), a subsample of ~1 kg coal prepared to a top-size of 4.75 mm is required, whereas for general analysis a final sample of 50–100 g crushed to less than 0.2 mm is sufficient.

Sample preparation procedures typically involve a fixed sequence of operations:

1. Extract a subsample for total moisture determination.
2. Air dry the gross sample (to ensure that the coal will flow smoothly through subsequent equipment). It should be noted that forced drying can have adverse effects, especially on coking properties; thus heating samples to more than 15°C above ambient temperatures should be avoided.
3. Reduce the particle size of the sample. The whole gross sample is crushed to some intermediate size (10, 5, and 3 mm) using a mechanical mill or crusher.
4. Mix the whole sample thoroughly to ensure homogeneity.
5. Reduce the mass of the gross sample (sample division) to a mass consistent with the present size of the coal, by using a mechanical sample divider.
6. Further crush the sample using a high-speed impact mill to attain the required particle size.

7. Finally, mix and divide to the mass required for the laboratory sample.

It should be noted that the coking properties of crushed coal samples deteriorate rapidly with time. Therefore, samples intended for such testing should be prepared immediately before analysis.

Coke sampling is marginally less problematic because the product from a single source derives from coal or blend of coals that have been prepared to a specification for ash, moisture, particle size distribution, etc. The final coke produced will be relatively homogeneous in all properties, with the exception of size distribution. Standard methods are available for coke sampling that reflects the somewhat less rigorous requirements for this material.

## Petrography and Chemical Composition

Coal is not a homogeneous rock. In coal seams, petrographers have distinguished with the naked eye more or less lustrous thin beds and regular accumulations that can be divided into four fairly well-defined classes called lithotypes – vitrain (brilliant layer), clarain (semibrilliant layer), durain (mat layer), and fusain (fibrous layer). When coal is examined through an optical microscope with reflected light under oil immersion, it is shown that coal is composed of discrete entities, called macerals, which result from the transformations of the original vegetal debris. According to their optical characteristics macerals can be classified into three groups:

- The vitrinite group originates from lignocellulosic tissues that are gelified by bacterial action. It is mainly composed of aromatic and hydroaromatic structures and is usually the most abundant maceral group. It often occurs as a matrix surrounding the other macerals and mineral constituents and has the property of swelling and agglomerating during the carbonization of medium-rank coals. Its density increases with rank from 1.2 to 1.7 g cm<sup>-3</sup>.
- The liptinite group is derived from organisms and organs that are relatively poor in oxygen such as algae, spores, pollens, cuticles, secretions. Chemically, it is characterized by a higher content in hydrogen and aliphatic structures. It is the lightest maceral with a density between 1.1 and 1.25 g cm<sup>-3</sup>. By thermal heating in an inert atmosphere, it is converted to volatile products, leaving little solid residue.
- The inertinite group often originates from vegetable matter that is partly burnt or has undergone lengthy aerobic oxidation before burial. Chemically,

it is mostly aromatic with a comparatively higher amount of carbon and lower amounts of hydrogen and volatile matter. It is the densest maceral (1.4–2.0 g cm<sup>-3</sup>). Most inertinite remains inert during the carbonization process, although the least reflective ones still retain plastic properties.

The maceral content defines the coal type: sapropelic, with >50% liptinite, or humic, more abundant, usually presenting a banded structure. On the other hand, based on the different optical properties of macerals, the reflectance of vitrinite is an essential characteristic used in coal identification and related to rank. A good analysis of maceral content provides knowledge about the chemical composition of a coal, their behavior in different conversion processes, and can also be used as a parameter of coal rank (see section on Petrographic analysis).

Thus, the chemical composition of the dominant organic part of a coal, mainly the amounts of carbon, hydrogen, and oxygen, which together comprise between 97% and 99% of the mass of pure coal, depends on the coal type, and has a clear evolution with coal rank, the carbon content increasing progressively from <65% for lignite to ~95% for anthracite. Hydrogen is a minor element, following an opposite trend. Oxygen decreases correspondingly from above 30% in lignites to <1% in the highest rank coals. No distinct trends are apparent for nitrogen (usually between 0.3 and 1.5%) and organic sulfur (0.3–2%). A progressive decrease in water and volatile matter contents (from >42 to <4%) goes parallel to an increasing rank. **Table 3** presents typical values for elemental analysis of coal precursors and coals of increasing rank, together with proximate analysis and calorific values.

The inorganic constituents of coal are the residues of plant components, minerals incorporated in coal seams, and rocks co-deposited or mixed with the coal during mining. As such, their chemical composition is enormously varied. The principal components found are quartz and minerals of clay, mica, and chlorite groups. Sulfide, carbonate, and chloride minerals, together with feldspars, barites, and titanium minerals, make up the remainder of the suite, along with lesser concentrations of minerals formed by weathering, such as limonite and sulfates of iron and calcium. Of particular interest is the content of sulfur minerals. Sulfur is an undesirable constituent of coal, and as such will attract a price penalty if present at greater than specified levels.

Virtually all other elements occur sporadically in coal. These 'trace' or 'minor' elements rarely constitute more than 1% of the mineral matter and frequently the proportion is much lower.

**Table 3** Composition of different rank coals

Coal	C (mass% dmmf)	H (mass% dmmf)	O (mass% dmmf)	N (mass% dmmf)	S (mass% dmmf)	Moisture (mass%)	Ash (mass% db)	Volatile matter (mass% db)	Calorific value (MJ kg <sup>-1</sup> )
Wood	50.0	6.0	43.0	0.5	0.5	15.0	1.0	70.0	16.61
Peat	57.0	6.0	34.5	1.5	1.0	13.0	3.0	59.0	18.56
Lignite	66.0	5.5	25.2	1.3	2.0	16.0	6.0	48.0	19.05
Bituminous									
hvb <sup>a</sup>	78.8	5.5	13.0	1.3	1.4	10.7	3.1	32.0	28.47
hvb <sup>a</sup>	84.7	5.4	7.3	1.8	0.8	4.7	5.0	35.5	31.40
hvb <sup>a</sup>	87.5	5.5	4.8	1.2	1.0	1.5	5.9	31.6	33.00

## Analysis and Tests

The suite of analyses required for a particular coal mainly depends on its intended end-use. Steam coals are defined through parameters related to their calorific value and impurities content having a strong impact on environmental pollution; metallurgical, or coking coals are better classified through specific tests related to their properties to transform to a good-quality coke for a particular application. Testing and assessing of a coal starts with a consideration of its rank, washability, hardness, and its inherent moisture content and is followed by analyses of its chemical, physical, rheological, and microscopic properties, and, finally, pilot tests. As with coal sampling, national and international standard methods for the analysis of coal and coke have been developed in order to define the quality of the material through chemical, petrographic, and empirical tests. These enable the producer to monitor variations in the quality of the product and the purchaser to assess the suitability of marketed coal for a process.

Instrumental methods are now becoming accepted as alternative techniques, provided they are shown to give equivalent results to the conventional test. These methods can allow a greater throughput of samples, with less operator dependence than conventional techniques, and often generate useful data that were not previously available. In fact, there are some instrumental companies, i.e., LECO Corporation, devoted almost exclusively to the development and sale of apparatus for chemical analysis – immediate analysis, elemental analysis, sulfur determination – calorific value, ash fusibility, and other technical tests of coals.

Knowledge of the total moisture of a coal is essential in commercial activities. Proximate analysis – determination of residual moisture, ash, and volatile matter in a dried sample of coal – is made for all samples received for coal utilization. Elemental analysis (C, H, N, O) and analysis of sulfur are necessary in order to have a better knowledge of the quality of a coal. Petrographic analysis provides information on the rank, quality, and blending of coking coals. Friability tests are necessary for the behavior of steam coals, and plasticity and swelling tests for the behavior of coking samples. The analysis of mineral matter gives information on the possibility of pollution problems and tests of fusibility on the ash behavior of combustion coals.

Most analyses of coal are carried out on air-dried samples and results are normally reported on the dry basis (db), as percentage of the coal after the moisture has been removed. When samples are compared on the basis of certain properties of the pure coal,

results are given in a dry, ash-free basis (daf). If more complete analytical data are available they can be given in a dry, mineral matter-free basis (dmmf), results being a measure of only the organic component of coal.

Other bases may be required for the expression of analytical data. Moist, ash-free basis (maf) assumes that the sample is free of ash, but with moisture (ASTM D388, Standard Classification of Coal by Rank, requires calorific value to be expressed on a moist, mineral matter-free basis (mmmfm)). The various national standards organizations present different formulae for the calculation of mineral matter (which is not a generally determined value); reference to their publications is necessary to determine which calculation is appropriate in given circumstances.

An exhaustive discussion of individual methods is outside the scope of this article. Thus, the more commonly reported tests are commented upon below.

## Moisture

The water in coal is bound in different forms to its constituents. It can be divided into three types: (1) Free moisture, also referred to as external moisture, superficial moisture, or the primary moisture fraction, which is present in large cracks and capillaries. Water bound in this way retains its normal physical properties. (2) Inherent moisture, also referred to as internal moisture or the secondary moisture fraction, whose vapor pressure is lower, since it is absorbed within the pore structure of the coal. (3) Water of constitution, which is mainly combined with mineral matter normally present in coal. This water is generally driven off only at temperatures higher than those normally used for the determination of moisture content. Standard methods do not make use of these terms and define: (1) the total moisture content of a coal; and (2) the moisture content of the coal analysis sample. Total moisture determination must be made over the sample as received in the laboratory, in an air-proof recipient. The determination consists in drying in an oven at 105°C till constant weight. Its value is of huge interest both in international and domestic coal trade (ISO 589, ASTM D3173).

This determination must be differentiated from that of the moisture of the sample for analysis that corresponds to a sample of coal equilibrated at the laboratory conditions (usually, 24 h). The methodology is the same and the value is that to be used in the calculations at the different bases.

The equilibration of a coal sample in laboratory conditions is absolutely necessary in order to facilitate handling of the sample in the following

operations, such as sizing – humid coal samples do not answer to riffing – or the Hardgrove grindability test (see below).

### Sizing

Size analysis is useful in assessing problems in coal transportation and handling. For larger sizes coals, hand or mechanical sieving or screening is undertaken; fines (<1 mm) are better screened in humid medium; while for ultrafines (<0.06 mm) optical or electrical field effect techniques are more appropriate.

Size reduction is carried out on the samples for analysis, depending on the specific analysis or test (i.e., <0.212 mm for chemical analysis, <4.75 mm for Hardgrove; <1 mm for petrographic analysis).

### Hardgrove Grindability Index

This index gives a value for the grindability of coal and coke. The numerical value is related to the number of revolutions needed to reduce a given amount to a determined particle size, relative to a standard (see ISO 5074 and ASTM D409). Grindability is related with rank, Hardgrove index reaching a maximum for coals with 80–90% of carbon. High values of Hardgrove index (50–80) are indicative of easier to grind materials while values in the order of 20–30 indicate a higher hardness of a coal.

## Chemical Analyses

### Proximate Analysis

The analyses of the air-dried equilibrated sample for moisture, ash, and volatile matter are collectively termed the proximate analysis. Fixed carbon is, by definition, the difference between 100 and the sum of the analytes (moisture, ash, volatile matter). The proximate analysis gives information on the classification of coal by measuring the relative percentage of volatile and nonvolatile organic matter as those of moisture and noncombustible mineral matter.

Determination of moisture was discussed above (ISO 589, ASTM D3173). Volatile matter – parameter used in coal classification – can be defined as the percentage of gaseous components of the coal, except moisture, loss at a high temperature in an inert atmosphere. Its determination is carried out under prescribed conditions (i.e., 7 min at 900°C) starting from an amount of normalized material around a mass of 1 g (ISO 562, ASTM D3175).

Ash is the solid residue from inorganic material after the complete combustion of coal. Its composition and amount depends on the analytical conditions (ISO 1171, ASTM D3174) that must be

strictly maintained in order to obtain comparable results. The ash content differs from the mineral matter content, both in their composition and in their mass (always lower). The mineral matter content is often calculated following the empirical formula of Parr:

$$\text{Mineral matter (\%)} = 1.08\text{Ash} + 0.55S_{\text{pyritic}}$$

The difference between both contents – ash and mineral matter – can lead to considerable errors, larger when the contents are larger. For less than 30 mass%, the error is ~1.3%, which rises to 4% when the ash content is around 25% and to 28% for inorganic contents of 70%.

The whole analysis can be done in an automatic apparatus designed to reproduce the analytical conditions of the established procedures. The apparatus follows a program and can work simultaneously with 20 samples. The conditions for determination of moisture are well accomplished, but some details on the determination of volatile matter (time) and ashes (temperature, 815°C) are not exactly the same and the tolerance (2%) is higher than that of the standard method (1%). Anyhow they are largely used in electrical utilities that need to make hundreds of analyses from different suppliers each day.

### Calorific Value

The gross calorific value is the amount of heat released by burning with oxygen a coal sample in a calorimeter under controlled conditions. A correction for the heat absorbed by the remaining ashes must be calculated. If the correction includes the latent heat of vaporization, the net calorific value, important in the coal market, is determined.

The measurement can be done both in isothermal or adiabatic calorimeters, the latter being preferred. For isothermal measurement (see ASTM D3286), the temperature of the calorimeter jacket is held constant and a correction for heat transfer from the calorimeter is applied, while in the adiabatic measurement (see ISO 1928 and ASTM D2015), the temperature of the calorimeter jacket is continuously adjusted to approximate that of the calorimeter itself.

The calorific value can be correlated with the fixed carbon content of the coal. It is a good parameter for coal classification of specific coal types and as a price determination index (\$ per MBtu) for commercial steam coals.

### Ultimate or Elemental Analysis

Analysis for the elementary constituents of coal follows techniques similar to those employed in organic

chemistry. It comprises analyses for carbon, hydrogen, nitrogen, sulfur, and oxygen, and altogether give the composition of the organic matter of a coal. Corrections must be made because, apart from nitrogen, carbon, sulfur, and oxygen can be found in impurities (as carbonates, sulfides, sulfates, clays), and hydrogen and oxygen are present in the sample moisture.

Carbon and hydrogen are determined through complete combustion at 1200°C. The gases (CO<sub>2</sub> and H<sub>2</sub>O) are absorbed, respectively, on anhydrous and NaOH and measured gravimetrically (see ISO 609, ASTM D3178).

Nitrogen is determined by the Kjeldahl method. Nitrogen is transformed in ammonium sulfate by treatment with concentrated sulfuric acid at 900°C. Afterwards it is liberated as ammonia in a steam stream that passes through a diluted acid solution and a titration with alkali (see ISO 332, ASTM D3179).

Sulfur occurs in both organic and inorganic combinations. For certain purposes a knowledge of total sulfur content is adequate; however, for coal preparation and conversion processes, determination of the forms of sulfur (organic, pyritic, and sulfate) is valuable.

The total sulfur content may be determined by one of several methods that convert it to sulfate by wet chemical analysis. One of these, the Eschka method, involves combustion of coal at 800°C in the presence of alkaline/oxidant medium (e.g., two parts of calcined MgO and one part anhydrous sodium carbonate); all sulfur is converted to sulfate that by the addition of barium chloride precipitates as barium sulfate, which is calcined to BaO and measured gravimetrically (see ASTM D3177). This is a standard method in many countries. Another is the 'high-temperature method' where the coal is burned in oxygen at 1350°C, converting all sulfur present into SO<sub>2</sub>. The SO<sub>2</sub> is then converted to sulfuric acid for titrimetric determination.

Pyritic sulfur may be determined by the estimation of pyritic iron, which involves a pretreatment with hydrochloric acid to eliminate the nonpyritic iron and then dissolving the pyritic iron in nitric acid.

Sulfate sulfur is estimated by solution in hydrochloric acid followed by gravimetric estimation of the dissolved sulfates.

Procedures to determine the sulfur forms – sulfates, pyritic, and organic sulfur – are well described in ISO 157 and ASTM D2492.

Automatic systems have been developed and are largely used in the simultaneous analysis of carbon, hydrogen, and nitrogen. Samples (up to 20) of 50–100 mg are burned and the evolved gases, CO<sub>2</sub>,

H<sub>2</sub>O, and N<sub>2</sub>, monitored by a thermal conductivity detector.

The oxygen content of a coal is an important rank parameter, the younger coals being richer in this element than the more mature coals. Oxygen is traditionally calculated by difference mainly for high-rank coals from a knowledge of the amount of other chemical components (C, H, N, and S), moisture, and ash contents. Techniques involving direct determination of oxygen avoid the effect of cumulative error in the analysis by difference.

The direct determination of oxygen has been and continues to be a problem as it does not have an easy solution. Laboratory microanalyzers for C, H, N, S, and O have been developed. They work over smaller coal samples (~1 mg) and the oxygen determination, based on chemical methods available, is carried out in a supplementary device, where the sample is pyrolyzed at 1350°C in a helium stream and reducing atmosphere. The resulting gases are passed over activated carbon, which converts oxygenated products into carbon monoxide. The CO is converted catalytically to CO<sub>2</sub> and then quantified by means of an infrared detector. The method is increasingly used mainly in analysis of low-rank coals, in coal weathering research, and analysis of carbon materials.

### Other Chemical Analyses

The chemical analyses of ash for major elements and a test in ash fusibility temperature give guidelines on coal utilization, defining the suitability of coal for different combustion or conversion systems. Analysis for minor elements is gaining impetus as greater interest is taken in the environmental consequences of coal uses. Typical ranges of concentration for major, minor, and trace elements are summarized in **Table 4**.

Multielement analytical techniques – atomic absorption spectrometry, inductively coupled plasma mass spectrometry, X-ray fluorescence, neutron activation analysis, etc. – are used. The experimentation can be done directly on the mineral matter of the coal sample after the removal of the organic matter by a prolonged treatment of activation with oxygen plasma (low-temperature ashing). Neutron activation is also applied to online analyses of coal and fly-ashes on feeding-belts in order to provide information on a continuous basis.

Chlorine can also occur in coal as organic and inorganic compounds, but only the total chlorine is normally determined. Formulae for calculating mineral matter contents arbitrarily assume 50% of the chlorine to be inorganic.

**Table 4** Concentration ranges of major, minor, and trace elements in coal

<i>Major and minor constituents</i>		<i>Trace elements</i>	
<i>Ash analysis</i>	<i>Ash (mass%)</i>	<i>Element</i>	<i>Concentration (<math>\mu\text{g per g coal}</math>)</i>
SiO <sub>2</sub>	40–90	Be	0.1–15
Al <sub>2</sub> O <sub>3</sub>	20–60	Cr	0.5–60
Fe <sub>2</sub> O <sub>3</sub>	5–25	Mn	5–300
CaO	1–15	Co	0.5–30
MgO	0.5–4	Ni	0.5–50
Na <sub>2</sub> O	0.5–3	As	0.5–80
K <sub>2</sub> O	0.5–10	Se	0.2–10
P <sub>2</sub> O <sub>5</sub>	<1	Cd	0.1–3
TiO <sub>2</sub>	<2	Sb	0.05–10
		Hg	0.02–1
		Pb	2–80

## Petrographic Analysis

The most widely used petrographic analyses of coal are maceral analysis and vitrinite reflectance analysis. Both are performed on representative samples ground to <1 mm in size and embedded in resin. The polished surfaces are then examined under a white reflected light microscope.

### Maceral Analysis

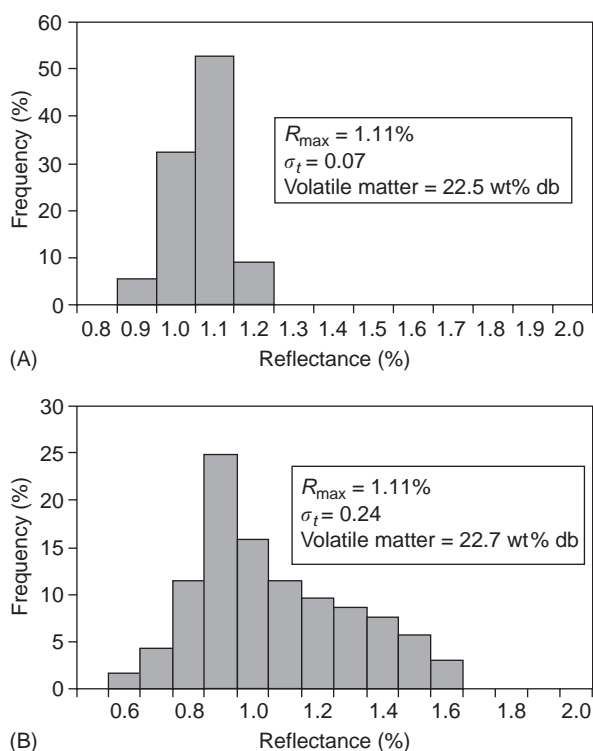

The relative proportion of petrographic components in a coal can be performed at a maceral level or maceral group level depending on the degree of detail desired. For most industrial applications the maceral group analysis is usually enough. For coals to be used in coking processes it might be desirable distinguishing between low- and high-reflecting inertinites since the former still retains plastic properties (see below). For a better discrimination of liptinite group macerals in low-rank coal the use of fluorescence light might be convenient. As with other coal analyses, several international and national standard procedures are available with minor differences among them and they describe with some degree of detail the procedure of pellet preparation, the total number of points counted, the magnification employed, the repeatability and reproducibility values, etc. (i.e., ISO 7404-3 and ASTM D2797). Oil immersion objectives are normally used to provide best identification conditions. For standard maceral analysis typically 500 points are recorded by point counting displacing the sample with a mechanical stage at regular intervals (0.5 mm). The results are expressed in volume percent based on the principle that the surface occupied by a given component in a randomly selected section is proportional to the volume of that component in the sample.

### Vitrinite Reflectance Analysis

The reflectance of vitrinite is a rank parameter that has well-established relationships with other chemical rank parameters such as volatile matter, C, and H contents. Among the advantages of the use of vitrinite reflectance as a rank parameter are that it follows a regular increase over the whole coalification scale and is not affected by maceral composition since it is recorded on individual particles. Reflectance is defined as the proportion of perpendicularly incident light reflected from a component compared to that reflected from a standard of known reflectance. Readings are taken with monochromatic light (546 nm) and oil immersion objectives (1.518 refraction index at 23°C) following the standard ISO 7404-5 procedure (see also ASTM D2798). Strict rank determination requires recording the readings on a single maceral from the vitrinite group – collotelinite – although for most industrial applications readings recorded on any maceral of vitrinite group might be sufficient.

Two types of readings can be taken on vitrinite particles: (1) random reflectance ( $R_r$ ) using nonpolarized light; and (2) maximum reflectance ( $R_{\max}$ ) using polarized light and turning the stage till the maximum reflectance is achieved. For low-rank coals,  $R_r$  and  $R_{\max}$  are equivalent. As coal rank increases vitrinite develops anisotropy yielding higher  $R_{\max}$  values than  $R_r$ . In both cases 100 readings selected using a regular frame are averaged to calculate mean reflectance values and to construct the reflectogram with distribution of vitrinite classes. Standard deviation must also be provided. Reflectance values typically approach to a Gaussian distribution for low-rank coals and standard deviation increases with the rank of the coal.  $R_{\max}$  is recommended for detailed studies on burial history of coal basins, whereas for most industrial applications random reflectance is preferred since its analysis is less time consuming.

Petrographic analysis is the only procedure to determine the various components of a coal blend, which is of foremost importance in coal utilization. In this case reflectance readings are taken on any vitrinite within the particle regardless the maceral on which the crosswire is landed. With this procedure the histogram plot reflects directly the proportion of the coals in the blend. The analysis yields the rank of the single-component coals and their amount. Coal discrimination is easy for blends of coals of rather different rank. Calculations may require histogram deconvolution for coals close in rank. A higher amount of readings is recommended for coal blend analysis.

**Figure 2** Histograms of the distribution of vitrinite in reflectance classes for a bituminous coal (A) and a complex coal blend (B).

As an example, **Figure 2** displays the histograms of the distribution of vitrinite in different reflectance classes for a bituminous coal and a complex coal blend with the same volatile matter content and mean vitrinite reflectance.

Both maceral and reflectance analysis may be performed by automated image analysis systems that process images acquired with a camera. They usually yield an average reflectogram of all components in the sample where thresholds must be established in a further step either manually or using more or less complex computer routines. The maceral group percentages are calculated as the area under the curve within two thresholds and the vitrinite reflectance value is based on the position of the peak assigned to vitrinite. Automated systems yield results similar to manual analysis for medium-rank vitrinite-rich coals, but problems remain with resin–mineral matter–lipinite thresholding for low-rank coals and inertinite–vitrinite thresholding for high-rank coals.

## Thermal and Rheological Properties

It is well established that only coals within a specific range of rank and type are suitable for coke production. Chemical analyses of the single coals, including ash and sulfur, are important parameters in

cokemaking, but criteria for selecting coals in coke manufacture are based on certain properties of coals that, when heated in an inert atmosphere, cause them to soften, become plastic, and coalesce into a coherent mass that swells and resolidifies to form a solid porous carbon material (coke). These particular types of coal are generally known as ‘caking coals’. The physical changes occurring in coal when heated in the temperature range of 350–550°C in the absence of oxygen are known as ‘plastic or thermoplastic properties’. The importance of such properties is related to the capacity of agglomeration between the reactive maceral constituents of the coal and the inert particles (some part of the inertinite maceral group and mineral constituents). On the other hand, the remaining coals are referred to as ‘noncaking’ coals and they produce a weakly coherent or noncoherent char. It is important to point out the difference between ‘caking coal’ and ‘coking coal’. The term ‘caking’ is reserved for coals that possess plastic (or agglutinating) properties in laboratory tests, while the use of ‘coking’ is related to caking coals in which plastic properties are so strongly expressed as to make them suitable for conversion in metallurgical and other industrial cokes. Caking coals are therefore strongly caking coals with a volatile matter content ranging between 19 and 32 wt%. Caking behavior can be assessed during rapid heating (100°C min<sup>-1</sup>), whereas coking behavior is assessed during slow controlled heating at a rate of 3–5°C min<sup>-1</sup>.

An appraisal of caking and related rheological properties is consequently not simple and usually requires measurement of several parameters. Distinct laboratory tests to assess these properties, swelling and caking, have been developed to simulate the coal behavior and the experimental conditions in coke ovens. Some of them have been standardized and are widely used to evaluate the suitability of a coal or coal blend for coke production. It has been reported that swelling and caking are therefore mutually reinforcing phenomena and that swelling is simultaneously the cause and the consequence of caking. It should be pointed out that coal blending has been adopted by the industry because of the limited availability and high cost of good coking coals and the continued demand for better quality coke for the blast furnace. Coal blends must be low in cost, produce a high-quality coke, and provide a safe oven pushing performance. They are composed of coals (four or more) differing in rank, rheological properties, geographical origin, and their proportion in the blend. As aids to coal selection and coke quality prediction, several mathematical models have been developed and extensively reported. Most of them

are based on parameters reflecting the rank, maceral behavior during carbonization (the concept of reactive and inert), and plastic properties of coal.

Some of the most common methods to evaluate the suitability of a coal or coal blend for coke production are the free-swelling index test, Gray–King assay, Roga assay, various dilatometer tests, and Gieseler plastometer test. In addition, research using larger amount of coal sample is also performed by means of a pilot coke oven.

### Free-Swelling Index

The free-swelling index (FSI), also called the crucible-swelling index, is the simplest test to evaluate whether a coal is of potential value for coke manufacture. It can be taken as a preliminary separation of coking and noncoking coals and it provides some measure of relative coking characteristics. It does not reflect, however, essential coking characteristics such as plasticity. This test involves rapid heating of a small sample of crushed coal in a standardized crucible to a temperature of  $\sim 800^{\circ}\text{C}$ . After heating, a small coke ‘button’ remains in the crucible. The cross-sectional profile of this coke ‘button’ is compared to a series of standard profiles numbered 1–9 with 1/2 increments – **Figure 3** (ISO 501, ASTM D720). The lower the profile of the coke ‘button’ formed, the less the free-swelling power and/or caking power of coal. An index of 0 is assigned to a noncoherent and pulverulent coke ‘button’ and indices of 1–3 are usually taken as the coal is only weakly caking. A high FSI (8–9) is also

**Figure 3** Reference profiles of the free-swelling index test.

undesirable for cokemaking, because the coke is too weak with thin walls of its pores.

### Gray–King Assay

It is a predominantly visual assessment of agglomeration and swelling properties when an unconfined sample of coal (with or without inert diluent) is heated in a horizontal oven. The coal sample is slowly heated in a tube at  $5^{\circ}\text{C min}^{-1}$  up to  $600^{\circ}\text{C}$ . The appearance of the resulting coke is examined visually and classified by comparison with a series of reference cokes designated as A, B, C,..., G (ISO 502). The coal may remain in powder form, either granular or weakly coherent (coke types A, B, C), or it may be fused, but reduced in volume (coke types D, E, F) – **Figure 4**. Coal given a well-fused coke is classified as type G. If coal has a very high swelling power, it is tested with variable proportions of electrode carbon. The proportion of added carbon

**Figure 4** Gray–King coke types and profiles.

**Table 5** Comparison between free-swelling index, Gray–King coke type, and Roga index

Free-swelling index	Gray–King coke type
0–1/2	A–B
1–4	C–G2
4 1/2–6	F–G4
6 1/2–8	G3–G9
8 1/2–9	G7 and above

Free-swelling index	Roga index
0–1/2	0–5
1–2	5–20
2 1/2–4	20–45
> 4	> 45

Data taken from Ward CR (1984) *Coal Geology and Coal Technology*. Oxford: Blackwell Scientific.

characterizes the coal and the coke type is designated as G<sub>1</sub>–G<sub>8</sub>. Although it is not determined under the same conditions, the Gray–King coke type corresponds broadly to the FSI (Table 5).

### Roga Index

This test, originally developed in Poland, indicates the caking power of coal under standardized conditions (ISO 335). It is based on pressing a coal sample mixed with a standard anthracite under a small load at 850°C for 15 min in a standard crucible. The cohesion of the resultant coke is then tested in a drum tumbler, and the Roga index determined as the percentage of coarse material remaining. A general correspondence exists between the FSI and the Roga index. A Roga index of 45 indicates a coking coal with an FSI of  $\sim 3\frac{1}{2}$  to 4; the stronger coking coals have Roga indices above 45 (Table 5).

### Dilatometer Tests

Dilatometers allow the study of two types of phenomena: (1) the behavior of coal during fusion and softening; and (2) the contraction of semicoke or green coke beyond the temperature of resolidification. The dilatometry-based tests measure the volume changes when a compressed pencil of coal, confined by a piston, is heated in a vertical retort (ISO 349, ISO 8264, and ASTM D5515). This type of test differs from those described above in that swelling is not free, either because the coal has first been agglomerated by compression and because the piston is under load. It uses slow heating (usually, 3°C min<sup>−1</sup>) in an attempt to simulate the behavior of coal in a coke oven. The most commonly used dilatometer is that developed by Audibert–Arnu. A detailed description of the sample preparation,

Audibert–Arnu dilatometer, and the experimental conditions used are given in the International Standard ISO 349.

The Ruhr dilatometer test (ISO 8264), used in Germany and many other countries, is a modification of the Audibert–Arnu dilatometer test. By this test, the coking capacity G or G-factor, used for coke quality prediction, is calculated.

### Gieseler Plastometer Test

In coke production, crushed coal passes through a fluid or plastic state to become a fused porous solid carbon material (semicoke). The temperature over which coal exists in this fluid state and the extent of fluidity development are critical factors in coke manufacture, because they are responsible for good adhesion between reactive components of coal and inert particles. These characteristics of a coal or a coal blend (softening, reduction in viscosity, resolidification) are tested by using a constant-torque Gieseler plastometer (a specific type of viscosimeter) as described in the ASTM D2639 standard procedure. In this test, the coal sample (5 g with a particle size less than 0.425 mm) is heated from 300°C to 550°C at a rate of 3°C min<sup>−1</sup>. The parameters derived from this test are: (1) softening temperature, the temperature at which the coal starts to be fluid; (2) the temperature of maximum fluidity, the temperature at which the fluidity of the coal reaches a maximum; (3) resolidification temperature, the temperature at which the fluid mass resolidifies; (4) plastic range, which is defined as the difference between the resolidification and softening temperatures; and (5) maximum fluidity, obtained as dial divisions per minute (ddpm). Maximum fluidity may also be reported as the logarithm (base 10) of that value. The maximum fluidity is one of the most important parameters used to characterize coals for cokemaking. Parameters maximum fluidity and plastic range are of great relevance in the compatibility of coals for blend preparation.

### Coking Pressure Measurements

During carbonization, the volatile matters that evolve as a result of the thermal coal decomposition try to escape through the different layers formed in coke ovens. There is certain resistance to the passage of the volatile products and, consequently, a pressure is developed against the chamber walls, which is known as coking pressure. Certain coals generate high gas pressures in coke ovens that cause operational difficulties during coke pushing and coke-oven wall damage, thereby shortening coke oven life. This

type of coking coals, namely dangerous coals, are not carbonized individually, but are used as components in industrial coking blends in order to adjust the volatile matter and fluidity of the blend and to improve coke mechanical strength. It is therefore necessary to be able to predict and assess the danger of a coal, and keep the coking pressure below certain limits in order to prolong the life of the coke oven.

Two basic methods of approach can be undertaken to determine the suitability of a coal or coking blend: (1) indirect coking pressure measurements at laboratory scale and (2) direct coking pressure measurements by larger-scale tests, using a few hundreds of kilograms of coal while trying to reproduce industrial conditions.

Generally, the first type of tests involves heating of a coal sample while it is compressed by a piston acted by a standard load. As carbonization proceeds, the pressure generated in the coal charge causes movement of the piston, which is monitored. Depending on the expansion and/or contraction values observed, coals can be classified as very dangerous, dangerous, or nondangerous (safe). Among the laboratory-scale tests developed to monitor dangerous coals, the Koppers test and its variants and the sole-heated oven test are briefly described. The principal advantages of such tests are the shorter time, lower cost, and a smaller amount of coal required for testing.

### Koppers Test

The Koppers test uses an oven with unidirectional heating from one side. By this test, carbonization is performed with a sample of 80 g of coal that is subjected to a constant pressure of 10 kPa by means of a piston and the change in volume is measured. Modifications to the early Koppers test have been introduced by INCAR (Spanish Patent No. 524.258, 1983) based on Mott and Spooner's modifications. They include the heating system and experimental conditions such as pressure on the charge, bulk density, and the rate and duration of heating. As a result of the research conducted on several coals and coal blends, a criterion was established to classify coals. Coals giving a contraction greater than 10 mm and no expansion can be considered to be not dangerous during carbonization.

### Sole-Heated Oven Test

An ASTM procedure specifies the conditions under which the expansion or contraction of coal or coal blends during carbonization can be measured (ASTM D2014). This type of coking oven has unidirectional heating from one side (the sole).

### Movable Wall Oven

Direct measurement of coking pressure can be obtained in a movable wall oven, which is widely used to estimate coking pressure of a coal and a coking blend. A characteristic feature of these ovens is that one wall is mounted on runners such that it can move, or tend to move, away from the other oven wall. Its movement is nowadays restrained by a load cell that measures the force necessary to prevent the wall movement. By monitoring this force during a coking cycle, the pressure exerted by the charge on the wall can be calculated. There is no standard oven and procedure, although all movable wall ovens work on the same basic principles. These ovens with 250–400 kg capacity have similar width to commercial ovens, so that heating regimes can be accurately reproduced on the pilot scale. In addition to coking pressure measurements, the amount of coke produced allows to run full-scale coke tests in terms of physical and mechanical properties and reactivity to carbon dioxide.

### Coke

Metallurgical coke is a macroporous carbon material of high strength and relatively large lump size produced by the carbonization of coals with a specific rank or of coal blends at temperatures up to 1400 K. In conventional coke production, coal blends crushed to  $\sim 80\%$  less than 3 mm particle size are usually carbonized in batteries of coke ovens. The ovens are indirectly heated through the side walls at a temperature of  $\sim 1300^\circ\text{C}$  over a period of 18–20 h. About 90% of the coke produced from coal in the world is used to maintain the process of iron production in the blast furnace where it has three major roles: (1) as a fuel, it provides heat for the endothermic requirements of chemical reactions and the melting of slag and metal; (2) as a chemical reducing agent, it produces gases for the reduction of iron oxides; and (3) as a permeable support, it acts as the only solid material in the furnace that supports the iron-bearing burden and provides a permeable matrix necessary for slag and metal to pass down into the hearth and for hot gases to pass upwards into the stack.

Of these three roles, the first two can be substituted by oil, gas, plastics, and coal, which are injected at the tuyeres as generating energy and a carbon source. Such a substitution brings about a reduction in coke rates for the blast furnace. (Coke rate is the weight of coke required to produce 1 ton of iron). However, there is no other satisfactory material available, which can replace, fully or partially,

metallurgical coke as a permeable support of blast-furnace charge.

An assessment of the coke performance in the blast furnace operating with or without injection technology should include those properties of coke that reflect its resistance to degradation under the chemical and thermal environments of the blast furnace. Such properties are related to lump size, shape and size uniformity, chemical composition, mechanical strength, and thermal and chemical stabilities. Thus, coke for the blast furnace needs to be a successful compromise between structure and properties. To ensure good blast furnace performance, coke should be moderately large, with a narrow size range, and have a high mechanical strength and a high resistance to abrasion and thermal shock in the blast furnace. Because of the many unknown factors, it is not possible to establish universal quality indices common to all blast furnaces, although typical specifications for metallurgical coke quality are available. It could be said that each blast furnace depending on design and operation requires a tailored coke.

Impurities present in coke (moisture, volatile matter, ash, sulfur, phosphorous, and alkali contents) affect its performance in the blast furnace by decreasing its role as a fuel in terms of amounts of carbon available for direct and indirect reduction roles and also its role as a permeable support.

As in the case of coal, all determinations included in proximate analysis (moisture, ash, and volatile matter contents) are the subject of national and international standards (ISO 579 for the determination of total moisture content; ISO 687 and ASTM D3173 for the determination of moisture in the analysis sample; ISO 1171 and ASTM D3174 for the determination of ash; ISO 562 and ASTM D3175 for the determination of volatile matter content). **Table 6** summarizes typical coke chemical properties for some operating blast furnaces in Europe.

### Physical Tests

The importance of the physical properties of coke is linked to the need to support the ferrous burden and to give a permeable matrix through which reducing gases can flow and molten material can percolate in the lower blast-furnace region. These physical properties are related to its size (mean and distribution) and its resistance to breakage and abrasion. Coke size is mostly controlled by screening (ISO 728, ASTM D293). A large mean size with a narrow size distribution maintains adequate permeability. Most operators consider a mean optimum size to be in the range of 50–55 mm with a lower limit ~20–30 mm and an upper limit ~70–100 mm.

**Table 6** Required chemical properties of blast furnace coke

<i>Chemical property</i>	<i>European range</i>
Moisture (mass%)	1–6
Volatile matter (mass% db)	< 1.0
Ash (mass% db)	8–12
Sulfur (mass% db)	0.5–0.9
Phosphorous (mass% db)	0.02–0.06
Alkalies (mass% db)	< 0.3

In: *Proceedings of the Third European Cokemaking Congress*, pp. 1–10. Gent, Belgium, CRM-VDEh.

Coke is a porous carbon material consisting of a network of pores of various dimensions and shapes, some of which are closed, but the majority of which are interconnected. Generally, porosity of industrial cokes is determined indirectly from the ratio of apparent and true relative densities, according to the equation

$$\text{porosity (\%)} = 100 \left( 1 - \frac{\text{apparent density}}{\text{true density}} \right)$$

A full description of the determination of apparent and true specific densities of lump coke is given in the ISO 1014 and ASTM D167 procedures.

Empirical mechanical strength tests, commonly used to measure resistance to size degradation, involve dynamic loading either in the form of shatter tests (ISO 6161, ASTM D3038), where breakage occurs by impact, or revolving drum tests such as ASTM Tumbler (ASTM D3402), MICUM, half- and extended-MICUM, IRSID, and JIS (JIS K2151) tests, where attrition takes place by a combination of breakage and abrasion. In Europe, the MICUM and IRSID (ISO 556 and ISO 1881) tests, which use the same equipment, are dominant. The JIS test is widely used in Japan and Australia, while the ASTM Tumbler is commonly used in North America. **Table 7** summarizes the cold mechanical strength methods for coke testing.

All these tests are based on the mechanical treatment of a specific amount of coke (10–50 kg) with a defined size (>60 to >20 mm) performed in a rotating drum under well-defined conditions (number of revolutions and rate). Afterwards, the coke is sieved and the different size fractions weighted. During mechanical treatments, coke fragmentation takes place by fissuring, cohesiveness, and abrasion. Two indices are normally derived from these tests: one referred to fissuring or cohesion and the other to abrasion.

**Table 7** Standard tests for assessing mechanical strength of coke

	<i>MICUM</i>	<i>Half-MICUM</i>	<i>IRSID</i>	<i>ASTM Tumbler</i>	<i>JIS</i>
<i>Standard procedure</i>	ISO 556	ISO 556	ISO 1881	ASTM D294	JIS K2151

### High-Temperature Tests

The importance of high-temperature properties of coke was established by the Japanese Steel Industry from the dissection surveys of three blast furnaces that were quenching whilst operating. As a result the reactivity of coke to carbon dioxide was considered one of the most important characteristics to assess the quality of coke and the suitability of its use in the blast furnace. A high reactivity of cokes is disadvantageous because of a higher specific consumption of coke in the blast furnace. In addition, the reactive coke is mechanically less resistant, affecting the conditions of the gas flow in the blast furnace. Coke reactivity is commonly determined using a method developed by the Nippon Steel Corporation (NSC), which has been adopted as an ASTM standard procedure (ASTM D5341). The method measures the solution loss reaction of coke by carbon dioxide at 1100°C for 2 h on a dried coke sample of 200 g ( $20 \pm 1$  mm in size) under standardized gas flow rate conditions. The coke residue is cooled in nitrogen and the weight loss after reaction is defined as the coke reactivity index (CRI). The gasified coke is subjected to a mechanical strength test in a drum (600 revolutions at 20 rpm). The coke postreaction strength or coke strength after reaction index (CSR) is defined as the percentage of coke >9.5 mm or >10 mm remaining after the mechanical treatment. For cokes produced under similar coking conditions,

there is a high degree of correlation between the two indices, CRI and CSR both determined by NSC (Nippon Steel Corporation) method. It has been established that CRI is strongly influenced by the rank and type and quantity of mineral matter of the parent coal and CSR is also primarily controlled by coal properties and in general by coking conditions and oven design.

The range of optimum values in coke quality parameters is wide and strongly dependent upon the characteristics and operational conditions of the blast furnaces. As an example, typical coke size, mechanical strength before and after reaction with CO<sub>2</sub>, and reactivity index of cokes used in different blast furnaces worldwide are given in Table 8.

### Coke Petrography

Optical microscopy, using polarized reflected light, has been recognized as a very useful tool and has played a major role in studies of carbonization mechanisms and coke quality properties. Examination of a coke polished surface under a microscope reveals the presence of certain parts without optical activity (isotropic coke) and others with optical activity (anisotropic coke). The anisotropic carbon exhibits yellow, blue, and purple areas of various sizes, <1–200 μm, and shapes (optical texture) with an interchange of color on rotation of the specimen,

**Table 8** Required physical and high-temperature properties of blast furnace coke in current operation

in association with the use of a retarder plate. Each color represents a given orientation of the aromatic lamellar molecules that constitutes the carbon matrix. To describe the different components of the optical texture of coke, different classifications and nomenclatures have been developed by research centers and industry. Most of them make a distinction between isotropic, mosaics of various sizes, flow-type anisotropy of various sizes and shapes, and inerts. Quantification of the optical textural components can be conducted by means of a point counting technique on a sample embedded in resin (e.g., ASTM D3997 and ASTM D5061).

By combining this microscopic technique with an image analyzer, the analysis program allows the determination of total porosity of coke, the number, the total perimeter, the average diameter, and the wall thickness of pores.

The use of optical microscopy for qualitative and quantitative analysis of the optical texture of coke is performed rather in the field of research on carbonization than in a full characterization of coke by the industry.

It is established that the rank and chemistry of the parent coal strongly influence the optical textures of cokes. Several studies show that the development of anisotropy (size, shape, and intensity) during carbonization varies mainly with (1) coal rank; (2) petrographic composition of the coals; (3) plasticity of the parent coal; (4) carbonization conditions such as rate of heating, soak time, and gas overpressure; as well as (5) the nature of additives used in the coal blends.

## COLOR MEASUREMENT

**J B Hutchings**, Bedford, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Color is a perception. It is the human psychological response to electromagnetic radiation within the wavelength range of  $\sim 380\text{--}710\text{ nm}$ . In normal daylight the peak response occurs at  $550\text{ nm}$ . Color is an interdisciplinary subject in both its fundamental and applied levels. This has resulted in the use of a number of units to describe spectral colors. These colors do not occur at a single wavelength, energy, or frequency, but over bandwidths. The approximate equivalents are shown in Table 1. These are the colors on a neutral surrounding that are seen by a person of normal color vision.

The color of a substance is due to emission, if the substance is self-luminous, or, if it is not self-luminous,

to selective absorption during transmission or reflection of incident radiation. There are many different physical and chemical causes of color production; these are outlined below.

### Simple Excitations and Vibrations

External energy supplied to the substance is converted into thermal motion, and atoms are raised to an excited state by promotion of electrons to higher-energy orbitals.

After a short time each electron returns to its normal orbital, and the energy released may be manifested as radiation of a particular frequency (Planck's law). Incandescence is caused by heating, for example, in wire filaments and carbon arcs. Electrical stimulation is one cause of such excitation of specific atoms in vapors and gases. This occurs in sparks and mercury vapor lamps. In fluorescent tubes, ultraviolet (UV) emissions from mercury vapor lamps are

**Table 1** The visible spectrum and the approximate equivalence of units used to describe it

Energy (eV)	Color of light	Wavelength (nm)	Frequency ( $\times 10^{14}$ Hz)	Color of material that absorbs the light in this band
	UV			
3.1	Violet	420	7.5	Greenish yellow
2.7	Blue	450	7.0	Yellow
	Bluish green	490		Red
2.4	Green	520	5.7	Magenta
2.2	Yellow	580	5.2	Blue
2.0	Orange	600	4.9	Cyan
1.8	Red	650	4.3	Bluish green
	IR			

converted into lower-energy visible emissions by phosphor coatings. The coherent light produced by helium/neon gas lasers results from gas excitation amplified by optical feedback. Chemical excitation occurs in analytical flame tests (e.g., the yellow of sodium), and in high-energy displays of auroras.

Most molecular vibrations are of relatively low energy, and therefore interact in the infrared (IR) region. The presence of hydrogen bonding in water and ice raises vibrational energies and some absorption takes place at the red end of the visible spectrum. Thus, when pure and present in bulk, water and ice are perceived to be blue.

### Transitions Involving Ligand Field Effects

Compounds of the s- and p-block elements are almost always white, because the electron transition energies fall in the UV region. However, many compounds of transition elements are colored because they have unpaired electrons in d- or f-orbitals. Transitions taking place between these orbitals require less energy, and thus emissions occur in the visible range. Such colored emissions can occur in transition-metal compounds such as minerals and paint pigments, and when the transition-metal ion occurs as an impurity, as in many gems and glasses. The color depends on the energy difference between the two levels. Thus, in some complexes, the color depends on the type of ligand. For example,  $[\text{Ni}(\text{NH}_3)_6]^{2+}$  is blue,  $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$  is green, and  $[\text{Ni}(\text{NO}_2)_6]^{2+}$  is brown-red.

### Transitions between Molecular Orbitals

Highly colored organic molecules, such as those used as dyes or food colorants, are complex and unsaturated. Electrons are held in conjugated systems, and their excited states occur at comparatively low

energies, leading to the absorption of light of visible wavelengths. Longer conjugated chains require lower absorption energies for excitation. Color shifts are also achieved where there are electron donors, such as  $-\text{NH}_2$  or  $-\text{OH}$  groups, or electron acceptors, such as  $-\text{NO}_2$  or  $-\text{C}=\text{O}$  groups, which pump electrons into or out of the conjugated system, respectively. Re-emission may occur as fluorescence.

The colors of a number of inorganic species arise from charge transfer. For example, the d-levels of Cr(VI) and Mn(VII) are empty and their compounds ought to be colorless. However, charge transfer leads  $\text{CrO}_4^{2-}$  and  $\text{MnO}_4^-$  to be strongly colored. These transitions also cause the intense colors in blue sapphire and ultramarine.

### Transitions Involving Energy Bands

In certain types of materials, electrons are distributed in energy bands. The form of the band depends on the particular atomic orbitals and the atomic spacing and geometry. Electrons available for bonding occupy various levels within the band. In metals, light excites electrons within the band, and energy is strongly absorbed. The electromagnetic radiation induces electric currents within polished metal surfaces, and light is strongly re-emitted. The absorption and re-emission efficiencies depend on optical energy. If the efficiencies are equal at all energies in the visible range, polished metals will be silver when illuminated by white light. Colloidal metal particles dispersed in a medium also produce energy bands as in, for example, ruby glass.

Gaps may appear in energy bands to form a lower-energy (valence) band and a higher-energy (conduction) band. The lowest energy that can be absorbed is determined by the gap size. Large band gap materials such as diamond (5.4 eV) cannot absorb visible light and are colorless. Yellow cadmium sulfide (2.6 eV) absorbs somewhat in the blue, and red mercury(II) sulfide (vermillion) (2.0 eV) is able to

absorb blue, green, and yellow light. Pure semiconductors possessing lower-energy gaps (say 1.6 eV) are black.

Doped semiconductors possess donor or acceptor atoms within their band gaps. These effectively decrease the gap size and allow energy absorption. Diamond consists of carbon atoms, each having four valence electrons, while nitrogen atoms have five valence electrons. Where a small percentage (say 0.001%) of the carbon atoms has been replaced by nitrogen donor atoms, spare electrons entering a donor level within the band gap can be donated to the empty conduction band. Broadening of the donor level by heating, for example, leads to absorption at the blue end of the spectrum, allowing the diamond to appear yellow. Conversely, boron, which has three valence electrons, creates an acceptor hole that is filled by an electron from the full valence band. The energy needed for the transfer is very small, and leads to a lower-energy absorption and a red diamond. Other examples of these mechanisms can be found in light-emitting diodes, and some lasers and phosphors.

Transparent crystals and glasses often appear colored because they contain color centers. These encompass another form of band gap phenomenon. Sodium chloride is an ionic crystal consisting of a three-dimensional (3D) array of  $\text{Na}^+$  and  $\text{Cl}^-$  ions. When  $\text{Cl}^-$  is missing from the lattice, the presence of a free electron in its place can restore electrical neutrality. This is an F-centre (after the German *Farbe* = color), which forms a trapping energy level within the wide band gap of this white semiconductor crystal. An electron can be raised from the valence band into the trap by  $\gamma$ -, X-, or UV-radiation. The energy level (2.7 eV) present within the trap of an irradiated NaCl crystal containing such a defect (color center) can absorb blue light and leads to a yellow–brown color. Other examples of materials containing color centers are amethyst, smoky quartz, some fluorescing materials, and lasers.

### Geometrical and Physical Optics

The dispersion of light may be achieved by refraction through a prism. This dispersion occurs because the refractive index  $n$  of the prism material and the velocity of light passing through it vary with frequency of the light. Anomalous dispersion results when light absorption occurs in an otherwise transparent material. The complex refractive index ( $N$ ) is used to explain the behavior of such a material:  $N = n + ik$  where  $i$  is the square root of  $-1$  (an imaginary number), and  $k$  is an absorption coefficient. At

wavelengths where absorption occurs, the resonating frequency of the absorber interacts with the frequency of the light, and there are changes in both  $n$  and  $k$ . Such effects are also found in rainbows, and cause the flashes of fire in diamonds.

Scattering occurs when light is deflected in all directions, after striking fine particles or an irregular surface. The presence of scattering particles is not necessary because all materials scatter light to some extent. When light is scattered by particles that are very small compared with the wavelength of the light, the amount of scatter is related to the inverse of the fourth power of the wavelength. Scattering accounts for the blueness of the sky and watered-down skimmed milk, for redness at sunset, and for many blue and green bird-feathers. The Mie theory must be used to account for the scattering effects of larger particles. This theory accounts for phenomena in which scattering intensity and wavelength depend on the angle of view.

The interference of polarized white light produces the colors found in optically anisotropic materials. This phenomenon is made use of in the analysis of photoelastic stress patterns. When a single monochromatic light source is arranged so that it produces two overlapping beams, a series of interference fringes of alternate light and dark bands is obtained. The bands are the result of the alternate reinforcement and canceling of the coherent beam. Colors produced by interference without diffraction include those in nonstructured systems such as soap bubbles and oil slicks, and in structured systems such as mother of pearl and hummingbird feathers.

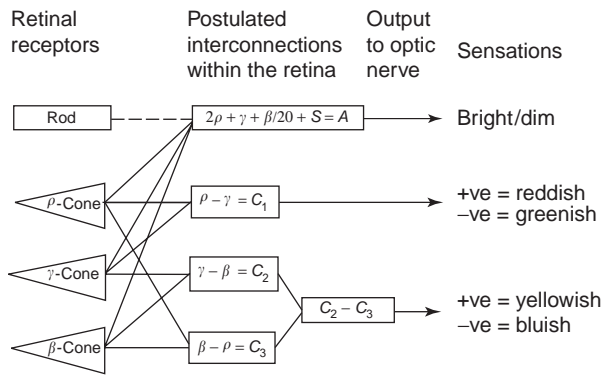

### Color Perception

The normal retina of the human eye has two types of detectors – rods, sensitive at low illumination levels, and cones, which operate under normal levels of daylight.

Their distribution is not uniform across the retina. There are three types of cone, each having different spectral sensitivities. The  $\beta$ -cones have peak sensitivities in the blue part of the spectrum, the  $\gamma$ -cones peak in the green, and the  $\rho$ -cones in the yellow–green. These different sensitivities to wavelength provide the basis for color vision.

There is a highly complex series of connections between the detectors and the fibers of the optic nerve, which takes the resulting signals to the visual cortex of the brain. There appear to be three types of nerve fiber, one of which is thought to carry the total achromatic or brightness information ( $A$ ), while the other two carry color information (**Figure 1**). The

**Figure 1** A postulated representation of the interconnections between receptors and the subsequent signals on which color sensations depend. (Reproduced with permission from Hunt RWG (1998) *Measuring Colour*, 3rd edn., p. 24. Kingston upon Thames: Fountain Press.)

brightness information consists of two parts, the rod response and all three cone responses weighted to compensate for the differing numbers of each type of cone. The color information from the retina is obtained from a series of signal differences and transmitted as two signals,  $C_1$  and  $(C_2 - C_3)$ .

These concepts can be used to indicate a visual basis of perceived color. Color can be thought of in terms of the brightness (by which an area appears to exhibit more or less light); hue (by which an area appears to be similar to one, or proportions of two, of the perceived colors red, yellow, green, and blue); and chroma, saturation, or colorfulness (by which an indication can be given of the amount or strength of hue present).

Good color vision is required for a number of tasks. These include judgments of color blending or matching, electrical and electronic circuit wiring, the setting up of color television sets, medical diagnosis, and medical/chemical analysis. Color vision standards exist for the armed services and public bodies concerned with transport.

Approximately 8% of men and 0.4% of women perceive colors in significantly different ways from the remainder of the population. Most of this color-deficient vision is inherited, but some can be acquired as a result of pathology, illness, or old age. The most common inherited causes relate to deficiencies or absence of the  $\rho$ - or  $\gamma$ -cones. The Ishihara charts may be used to detect the presence of such conditions. These charts consist of a number of plates made up of differently colored spots, which form numbers that may wrongly be described or not detected at all. This is a first screening for detection of a color vision deficiency.

Color vision probably evolved so that man could distinguish fruit from its surroundings. Our color

vision is not absolute but relative to other conditions in the environment, and this greatly assists in the recognition of the colors of objects in different viewing conditions. In consequence, failure to provide a consistent, rigorously observed set of conditions when the color of an object is being assessed or measured can lead to inconsistencies because of metamerism and other effects. Metamerism occurs when two colors match under one set of viewing conditions, but fail to match under a different set. Metamerism can be of four types: illuminant, observer, geometric, and field size.

## Measurement Principles and Instrumental Design

When viewing any object by reflection or transmission, three factors must be present for there to be a color: a light source, the object, and a viewing mechanism. If changes occur in any of these elements the color may change. Hence, any color measurement system must include a specification of these factors.

Color cannot be measured because it is perceived in the brain. However, it can be specified instrumentally using additive or subtractive mixing to produce a color that matches the object color. In the former, a match to most colors can be made by the additive mixing of light of the three primary colors. A measure of the intensity of the three primaries provides a specification of the color. Primary colors are defined such that none can be matched by mixtures of the other two. The principle of additive mixing is the basis of the common tristimulus and spectrophotometric methods of measurement.

Before these concepts could be developed to a generally acceptable measurement method, some agreement of the visual performance of a 'Standard Observer' was necessary. Observers with normal color vision obtained color matches for a series of wavelengths from 400 to 700 nm using additive mixing. The primaries were three monochromatic lights. The amount  $C$  of each color  $[C]$  was matched using amounts  $R$ ,  $G$ , and  $B$  of each particular stimulus  $[R]$ ,  $[G]$ , and  $[B]$ , where  $[R]$ ,  $[G]$ , and  $[B]$  represent red, green, and blue radiations, respectively. That is:

$$C[C] = R[R] + G[G] + B[B]$$

For most problems, it is convenient to separate the color quality, represented by the proportions of  $R$ ,  $G$ , and  $B$ , from the total intensity of light, represented by the absolute values of  $R$ ,  $G$ , and  $B$ . This is done by dividing  $R$ ,  $G$ , and  $B$  in turn by  $(R + G + B)$  to

give:

$$1.0[C] = r[R] + g[G] + b[B]$$

where  $r = R/(R + G + B)$ ,  $g = G/(R + G + B)$ ,  $b = B/(R + G + B)$ , and  $r$ ,  $g$ , and  $b$  are chromaticity coordinates.

Before a match can be obtained at a number of wavelengths the spectral color has to be desaturated. That is, one of the three stimuli has to be added to the color being matched. For these colors one of the coordinates is negative. The use of three unreal primaries ( $X$ ,  $Y$ ,  $Z$ ) was proposed to overcome this disadvantage. These define, effectively, the three cone responses of an observer with normal color vision, using a standard subtended viewing angle. The resulting chromaticity coordinates ( $x$ ,  $y$ ,  $z$ ) are always positive. If two are specified the third can be calculated. Hence, a two-dimensional ( $x$ ,  $y$ ) chromaticity diagram can be plotted as in **Figure 2**. In this, spectral colors are shown as a spectrum locus. The line joining the two ends of the spectrum locus is the purple boundary, nonspectral colors that are mixtures of long and short wavelengths from the two ends of the spectrum. Two sets of unreal primaries have been specified corresponding to  $2^\circ$  and  $10^\circ$  subtended angles of viewing.

All colors can be located within the area enclosed in the ( $x$ ,  $y$ ) chromaticity diagram. The chromaticity

**Figure 2** The 1931 CIE ( $x$ ,  $y$ ) chromaticity diagram for a  $2^\circ$  observer, showing the Planckian locus and the chromaticities of standard illuminants A, C, and  $D_{65}$ .

of any color resulting from a mixture of two other colors falls on the line joining their chromaticities. Deep, spectrum-like colors have chromaticities near to the spectrum locus (or the line of purples). Paler, less chromatic colors fall nearer to the white point. The standard illuminant used in the measurement governs the position of the white point, which defines the position of the achromatic point. This can be defined in comparison with a Planckian radiator. As the temperature of such a body is increased, the color of its emission changes from red at  $\sim 1600$  K, to whiter at 4000 or 5000 K, to bluer at 8000–10 000 K. The locus of chromaticities of Planckian radiators is plotted in **Figure 2**. Although the Planckian radiator itself is impractical as a light source, it provides a color temperature reference against which more practical sources may be judged. The Commission Internationale de l'Eclairage (CIE) has defined a number of standard illuminants, and those most commonly reported are illuminants A, C, and  $D_{65}$ . Illuminant A is provided by a gas-filled tungsten lamp operating at a color temperature of 2856 K. Illuminants C and  $D_{65}$ , closer to ordinary daylight, have respective color temperatures of approximately 6774 and 6500 K, respectively.

A definition of a color stimulus includes the chromaticity and a relative intensity measure, the luminance factor. This is determined by the value of  $Y$ . This primary has a spectral form which is the same as the eye's overall sensitivity in daylight. Thus, a color can be specified by the three dimensions ( $x$ ,  $y$ ,  $Y$ ).

### Tristimulus and Spectrophotometric Measurement

The tristimulus colorimeter is the simplest means for instrumental color specification. A light source, filters, and a photodetector are combined such that together they yield a direct evaluation of the tristimulus values  $X$ ,  $Y$ , and  $Z$ . A spectrophotometer may also be used for color specification. That is, a spectral reflectance or transmittance curve ( $R$ ) can also be converted into  $X$ ,  $Y$ ,  $Z$  data. The curve ( $R$  versus wavelength  $\lambda$ ) is integrated over the visible range, with the spectral emission of an illuminant ( $E$ ), and the standard observer functions ( $\bar{x}$ ,  $\bar{y}$ ,  $\bar{z}$ ). The areas under the resulting curves yield the values of  $X$ ,  $Y$ , and  $Z$ ; that is:

$$X = k \int_{380}^{710} RE\bar{x} d\lambda, \quad Y = k \int_{380}^{710} RE\bar{y} d\lambda,$$

$$Z = k \int_{380}^{710} RE\bar{z} d\lambda$$

where  $k$  is a constant chosen so that  $Y=100$  for a perfect white. The spectral curve produced by a spectrophotometer may also yield useful information regarding possible chemical mechanisms or color-change kinetics of the system under investigation.

There are four instrument geometries recommended by the CIE. Quoting the illumination angle ( $^\circ$ ) first, and the viewing angle second, they are designated: 45/0, 0/45, and, where integrating spheres are used, diffuse/0 and near-0/diffuse. The 45/0 and 0/45 geometries by definition exclude the spectral component of the reflected light. Instruments using diffuse illumination or viewing can often be set up to include (SPINC) or exclude (SPEX) this component.

All measurements are made relative to a 'white standard', which the CIE nominate to be a perfect diffuser. Such perfection does not exist, but compensation for this can be made during measurement and calculation. A colored substandard is sometimes used to increase measurement reliability and sensitivity. This technique has been found particularly useful when interlaboratory color-quality specification procedures are being established. Instrumental performance may be checked with highly stable reflection or transmission standards.

The perfect sample for reflectance measurement is one that is flat, uniform in color, perfectly matt, and opaque. Results from nonperfect samples will be subject to error, and appropriate measurement techniques must be used. For example, the relationships between illumination, sample, and measuring areas are important to the successful color measurement of translucent materials.

Color measurements can be made of fluorescent materials, which absorb energy at one wavelength and re-emit it at another. A dual monochromator spectrophotometer (i.e., a spectrofluorimeter) can be used to illuminate the sample with monochromatic radiation, and record the energy reflected plus that re-emitted at each wavelength. In this way, a total radiance (reflected plus emitted energy) curve characteristic of the material can be built up. Values of  $X$ ,  $Y$ , and  $Z$  are calculated in the normal way. A simpler approach involves illumination of the sample with a white light source that emits the approximate amounts of near-UV wavelengths occurring in daylight. Tristimulus values of the resulting radiance can then be measured using tristimulus or spectral techniques.

A statement of the measurement geometry, standard illuminant, and standard observer ( $2^\circ$  or  $10^\circ$ ) must be a part of the color specification. When comparing results made on different occasions, or at different laboratories, or when comparing instrumental

measurements and visual assessments, great care must be taken to ensure that all measurement and calculation details correspond.

### Digital Analysis

The advent of digital analysis presents the opportunity for measurement of products and scenes in terms of total appearance analysis. That is, in terms not only of average color, achieved by conventional instrumentation, but also in terms of a detailed examination of the type of color variation that occurs across the surfaces of biological materials. Using color-calibrated digital technology measurements of gloss, surface texture (as well as visual structure) can also be attempted on irregular 3D materials, such as fruit and vegetables. The technology for specifying total appearance is based upon the digital camera that can capture images rapidly in digital format. These digital images can be easily processed, duplicated, modified, or transmitted via a network.

Unfortunately, camera  $R$ ,  $G$ ,  $B$  sensors do not have the same spectral sensitivities as the CIE standard observer. Hence, in order to measure an object in terms of device independent color from a digital camera, there is a need to correlate the camera  $RGB$  signals and CIE  $XYZ$  values. The most common technique for digital camera characterization consists of presenting the camera with a series of color patches in a standardized reference chart with known  $XYZ$  values and recording the averaged  $RGB$  signals for each patch. Polynomial fitting techniques are then applied to interpolate the data over the full range and to generate inverse transformations. An overall accuracy of  $\sim 0.5\text{--}2.0 \Delta E^*$  units is obtainable.

### Uniform Chromaticity Space and Uniform Color Scales

The  $(x, y)$  chromaticity diagram is not perceptually uniform. Colorant-using industries have long sought a color space in which a unit distance can be interpreted as equivalent to a unit of visual perception. The CIE-recommended space (CIE 1986) includes the 1976  $(u', v')$  uniform chromaticity diagram. The transformations are:

$$u' = 4X/(X + 15Y + 3Z) = 4x/(-2x + 12y + 3)$$

$$v' = 9Y/(X + 15Y + 3Z) = 9y/(-2x + 12y + 3)$$

Plotted in this space (Figure 3) are lines that are equivalent to equally perceivable differences. The ratio of the lengths of the longest and shortest lines, a measure of linearity, is  $\sim 4:1$ . The ratio is 20:1 for the untransformed  $(x, y)$  space.

The CIE has recommended two ways of combining luminance factor and chromaticity information.

**Figure 3** The CIE ( $u'$ ,  $v'$ ) chromaticity diagram showing lines of equally perceivable differences. (Reproduced by permission from Hunt RWG (1998) *Measuring Colour*, 3rd edn., p. 60. Kingston upon Thames: Fountain Press.)

These are the CIE 1976 ( $L^*$   $u^*$   $v^*$ ), or CIELUV, and the CIE ( $L^*$   $a^*$   $b^*$ ), or CIELAB spaces. The former was primarily intended for industries involved with additive color mixing, such as lighting and television. This space is obtained by plotting  $L^*$ ,  $u^*$ , and  $v^*$  at right angles to each other:

$$\begin{aligned} L^* &= 116(Y/Y_n)^{1/3} - 16 \quad \text{for } Y/Y_n > 0.008856 \\ L^* &= 903.3(Y/Y_n) \quad \text{for } Y/Y_n \leq 0.008856 \\ u^* &= 13L^*(u' - u'_n) \\ v^* &= 13L^*(v' - v'_n) \end{aligned}$$

where  $u'$  and  $v'$  are defined as described above, and where  $u'_n$ ,  $v'_n$  are the values of  $u'$ ,  $v'$  for the appropriate reference white.

The 1976 CIELAB space is obtained by plotting  $L^*$ ,  $a^*$ , and  $b^*$  at right angles to each other:

$$\begin{aligned} L^* &\text{ is defined as above} \\ a^* &= 500[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}] \\ b^* &= 200[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}] \end{aligned}$$

where  $X_n$ ,  $Y_n$ , and  $Z_n$  are values of  $X$ ,  $Y$ ,  $Z$  for the appropriate reference white.

Hue-angle ( $h_{uv}$ ), saturation ( $s_{uv}$ ), and chroma ( $C_{uv}^*$ ) may be calculated within CIELUV space. The CIELUV hue-angle is given by  $h_{uv} = \arctan(v^*/u^*)$ , where  $\arctan$  means 'the angle whose tangent is...'. Hue-angle is the angle from the  $u$ -axis moving anticlockwise.

The CIELUV chroma is given by

$$C_{uv}^* = (u^{*2} + v^{*2})^{1/2} = L^* s_{uv}$$

where  $s_{uv}$  = CIE 1976  $u$ ,  $v$  saturation =  $13[(u' - u'_n)^2 + (v' - v'_n)^2]^{1/2}$ .

Values of hue-angle and chroma can be similarly calculated for CIELAB space. Both the CIELUV and CIELAB spaces approximate to the Munsell system for the uniform spacing of colored samples of painted papers.

Many commercial colorimeters utilize variants of the Hunter 1958 (Lab) space. The coordinates are:

$$\begin{aligned} L &= 10Y^{1/2} \\ a &= \frac{17.5(1.02X - Y)}{Y^{1/2}} \\ b &= \frac{7.0(Y - 0.847Z)}{Y^{1/2}} \end{aligned}$$

where  $X$ ,  $Y$ ,  $Z$  are the 1931 CIE tristimulus values. Axes  $L$ ,  $a$ , and  $b$  are mutually perpendicular. Changes in  $a$  and  $b$  represent approximately the opponent nature of our visual response. Axis  $a$  represents the change from green ( $-a$ ) to red ( $+a$ ); axis  $b$  from blue ( $-b$ ) to yellow ( $+b$ ). An increasing value of  $L$  represents an increase in whiteness or lightness. Neutral colors are close to ( $a=b=0$ ). Similar associations apply to  $u'$ ,  $v'$ , and  $L^*$  in the CIELUV system and to  $a^*$ ,  $b^*$ , and  $L^*$  in the CIELAB system. Hue-angle ( $\arctan b/a$ ), and saturation index  $[(a^2 + b^2)^{1/2}]$ , give descriptive color information.

The fundamental units of color measurement are  $X$ ,  $Y$ ,  $Z$  and hence ( $x$ ,  $y$ ,  $Y$ ) space. All other color measurement spaces are derived from them.

### Subtractive Colorimetry

The methods described above are based on additive color mixing, but color can also be specified using subtractive colorimetry. Where the sample is transparent, colored glasses are used to subtract light from a standard source until the resulting color visually matches that transmitted by the sample.

Opaque colors can be similarly measured, by using the lamp to illuminate both the sample and the surface of a white diffuse reflector. The glass filters are then adjusted to produce a matching color on the diffuser.

The Tintometer system glasses are magenta (called red) to absorb green light; yellow to absorb blue; and cyan (called blue) to absorb red light. The glasses of each color are arranged in a numerical scale from practically colorless to highly saturated. The sample

color can be specified by the number of units of red, yellow, and blue required to make the match. In certain tintometers a visual match is made using two of the scales and a light intensity control. The results can be converted into  $X$ ,  $Y$ ,  $Z$  values.

### Color Difference Calculation

A number representing the difference between two colors can be calculated in any of the coordinate systems described above. The equation is based on the square root of the sum of the squares of the differences in each axis. For example:

$$\Delta E_{(\text{CIELAB})} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

The near-linear nature of (Lab), CIELUV, and CIELAB spaces make color difference calculation more meaningful through the whole of color space. More sophisticated equations yielding greater precision have been developed for specific industrial applications.

### Color Organization

Whatever the system of color measurement or color description ordering in 3D space is essential. In terms of the measurements described above relative values of  $L^*$ ,  $a^*$ ,  $b^*$  are indicated in **Figure 4** together with directions of increasing hue and chroma. However,

**Figure 4** The three dimensions of color measurements and color order systems.

color can also be organized, and hence specified, according to a color order system. Many such systems have been produced and those most well known and widely used are the Munsell System and the Swedish Natural Color System (NCS). Associated with these systems are atlases consisting of books of chips, which cover a wide color range, organized in logical sequences, also indicated by the scheme shown in **Figure 4**.

The Munsell color dimensions are hue ( $H$ ), value ( $V$ ), and chroma ( $C$ ). The Hue circle consists of 10 major hues, each divided into 10 visually equal steps. The central achromatic  $V$  (lightness) axis consists of 10 visually equal steps, extending from ideal black = 0 to ideal white = 10. The radial distance from this axis indicates an increase in  $C$ ; that is, an increase in hue content and departure from grey.  $C$  is zero at the achromatic axis, and increases in visually equal steps to 10, 12, 14 or more for particularly saturated colors. The Munsell atlas consists of pages of colored chips, one page for each hue. Chips are arranged so the vertical axis of the page represents an increase in  $V$ , the horizontal axis an increase in  $C$ . The Munsell description of a yellow-red color of hue 3YR, value 5 and chroma 6 is 3YR 5/6. Interpolation between whole units is possible, and single decimal places may be used where appropriate. Some product-control systems involve the use of two or more Munsell colors on a spinning disk. Their relative areas are changed until a color match is obtained. A large range of colors within the color saturation limits of the disks can be produced.

The Swedish NCS is based upon Hering's postulate that all colors may be placed in a system with reference to six elementary color sensations. These are: whiteness ( $V$ ), blackness ( $S$ ), yellowness ( $Y$ ), redness ( $R$ ), blueness ( $B$ ), and greenness ( $G$ ), again as indicated in **Figure 4**. Any one color may be specified in terms of the percentages of two chromatic and two achromatic attributes. Thus, a particular color can be described as 2030-Y90R, where 20 is the percentage blackness  $s$ , 30 is the percentage chromaticity  $c$  (where  $c$  is the total % of chromatic colors, say red and yellow), and Y90R is the hue of containing 10% yellowness and 90% reddishness. Note, the percentage whiteness normally omitted from the specification =  $(100 - 20 - 30)\%$ .

The conditions necessary for the use of color chips are relevant to all visual color-matching and assessment procedures. Such tasks must be done by individuals with normal color vision, using standard viewing and lighting conditions. The illumination should be white and diffuse, and there should be no interference from extraneous light sources, or reflections from the ceiling or other objects in the room.

The lamp often used for visual assessment is the artificial daylight fluorescent tube. This produces an emission spectrum intended to imitate approximately that of the standard D65 illumination specified in BS 950: 1967 part 1. To eliminate gloss effects, a  $0^\circ/45^\circ$  (or vice versa) relationship must be maintained between the illumination, the sample and the viewer. The sample should be placed on a neutral mid-grey to white background. The sample is assessed against one chip at a time, a grey mask being placed over other chips on the atlas page.

## Applications of Color Measurement

There are three main uses for color measurement. A major use is in systems in which pigments or dyes are manipulated to produce a product of specified or matching color. The second use is for the specification of a color when establishing a commodity standard, or for reference during, for example, the storage trial of labile material. The third use provides a means of understanding the human response to a product or visually perceived situation.

A number of interactions take place when light impinges upon a material. These determine the color and appearance of the material. The interactions take place (1) from the surface (specular and diffuse reflection, and refraction into the body of the material), (2) within the material (internal diffusion or scattering and absorption), and (3) through the material (regular and diffuse transmission).

The ability to handle, specify, and predict scattering and absorption properties is vital to the solving of many practical problems. An example is the prediction of colorant concentrations that will produce a match for an existing color. In some industries it is necessary to specify translucency. These problems can be approached using the Kubelka–Munk concept of a colorant layer of turbid material, such as a paint film. This postulates two light fluxes traveling in opposite directions across a thin layer within a strongly light-scattering material. The layer is thick compared with the size of pigment particles, but thin compared with the sample thickness. It has an infinite lateral dimension. As each light flux passes through the layer, it is affected by the absorption coefficient ( $K$ ) and the scattering coefficient ( $S$ ) of the material. The treatment is relevant to monochromatic radiation, and it does not allow for light lost through Fresnel reflection at the interface between the air and the medium. Also, the pigments are assumed to be randomly orientated, and the differential equations are only concerned with diffuse light traveling in two directions.

The upward flux ( $j$ ) is decreased by absorption  $-Kjdx$ , decreased by scattering  $-Sjdx$ , and increased by backscatter from the downward-proceeding flux  $+Si dx$ . Hence, the total change in the upward flux is:

$$dj = -(K + S)j dx + Si dx$$

Similarly, the downward-proceeding flux ( $i$ ) is changed by:

$$-di = -(K + S)i dx + Sj dx$$

The most quoted solutions to these equations, for a sample thickness  $X$ , concern the following relationships:

$$\frac{K}{S} = \frac{(1 - R_\infty)^2}{2 R_\infty}$$

$$a = \frac{1}{2}R + \frac{R_0 - R + R_g}{R_0 R_g} = \frac{(S + K)}{S}$$

$$R_\infty = a - b$$

$$T_i^2 = (a - R_0)^2 - b^2$$

$$SX = \frac{1}{b} \operatorname{arc} \coth \frac{1 - aR_0}{bR_0}$$

where the reflectance ( $R$ ) of a colorant layer is backed by a known reflectance ( $R_g$ );  $R_0$  is the reflectance of a layer with an ideal black background,  $R_g = 0$ ;  $R$  is the reflectance of an infinitely thick layer of the material;  $T_i$  is the internal transmittance;  $b = (a^2 - 1)^{1/2}$ ; and  $\operatorname{arc} \coth$  is an inverse hyperbolic function. Tables are widely available for calculating such hyperbolic functions. Two measurements of a thin layer of the sample, over backgrounds of white and black, enable  $K$  and  $S$  to be calculated.

Much work has been done in the field of colorant formulation. Where  $K$  and  $S$  behave linearly and additively with dye and scatterer concentrations, colorant formulation may be possible using the ratio  $K/S$ . Where this does not occur,  $K$  and  $S$  can be treated independently.

The Kubelka–Munk theory does not take into account the reflectance from the front surface of the sample, nor the diffuse light incident upon this surface from the inside. Part of the light approaching the surface from a particle within the sample is scattered back into the sample. If the ray approaches the surface at an angle greater than the critical angle it will be totally internally reflected. Light loss can be substantial. For example,  $\sim 50\%$  of the light attempting to emerge from a boundary of refractive index ratio of 1.33 (air and water) is back-reflected. A correction

for reflectance has been developed by Saunderson:

$$R_c = \frac{R_m - k_e}{(1 - k_e)(1 - k_i) + k_i R_m - k_e k_i}$$

where  $R_c$  is the corrected reflectance,  $R_m$  the measured reflectance,  $k_e$  the fraction of incident light reflected externally, and  $k_i$  the fraction lost internally.

Methods are available for fine-tuning dye and pigment mixes by, for example, optimizing tristimulus values or using simplex methods. Such methods can be used to minimize metamerism and pigment costs. The many problems of dye and pigment formulation can be surmounted using specific equations for specific applications.

The second group of color measurement applications involves their use as standards or references where the original material might not be available for comparison. An example of the former includes standards for traffic light glasses (*Colors of Light Signals*, CIE publication 02.2). Measurements can be used as references during color change. Examples are weathering of paint and the comparison of the effect of treatment variables during food production trials. As for all color measurements, sample preparation must be appropriate to the form of the sample, and testing methodology must be rigorously consistent and shown to be reproducible.

The third application is directed toward the understanding of visual properties. For example, the effect of chemical changes on a sample color can lead to methods of defining the state of its chemistry. Tristimulus measurements have been used to monitor separately the progress of anthocyanin loss and browning increase occurring simultaneously in wines. Controlled oxidation and reduction reactions in tuna meat have been used to monitor the state of the pigment in the flesh, and to indicate damage inflicted during production.

An example of understanding in a psychophysical situation is provided by expert wine taster judgments. Tasters commented on the edge or rim color of four types of red wine. This property becomes apparent when the wine is swirled in the glass. Transreflectance spectrophotometric measurements were made on each wine using cells from 0.25 to 10 mm deep. Tristimulus properties were calculated from the spectra for the 2° observer and illuminant C. Using these measurements alone, it is difficult to visualize either the subtleties of color change with depth, or the color differences between the wines. However, Figure 5 shows that this situation can be remedied by superimposing Munsell constant hue and constant chroma lines onto the chromaticity locus of the wines. The change of color with cell depth

**Figure 5** Change of chromaticity with cell depth for four wines. From transreflectance measurements using a near 0°/diffuse instrument geometry, illuminant C, 2° observer. Cell 1, depth 0.25 mm; cell 2, depth 1 mm; cell 3, depth 2 mm; cell 4, depth 5 mm; cell 5, depth 10 mm. Lines of Munsell constant Hue and Chroma have been superimposed. (Reproduced with permission from Hutchings JB (1999) *Food Color and Appearance*, 2nd edn. Gaithersburg, MD: Aspen Publishers.)

is indicated by the number of constant hue lines crossed as cell depth is increased. The claret and the red wine change more than the port. Thin layers of claret and red wine are purpler than the chianti and port, because the depth-change chromaticity loci cross into the red–purple (RP) Munsell zone. Similarly, port is browner, because its locus enters the yellow–red (YR) zone. The chianti, noted as having slight browning on the rim, is not as purple in thin layer as the red wine or claret. This agrees with the observed order of purpleness of the thin layer when the wines are swirled in the glass – claret (most), red, chianti, port. Hence, tristimulus measurements can provide leads to psychophysical perception mechanisms in defined situations.

This approach, in which we are attempting to understand the color vocabulary of the expert, is being extended to the understanding of the vocabulary of total appearance. For example, consumer concepts such as ripeness of bananas and apparent flavor strength of orange juice are being approached using color calibrated digital analysis. Thus, the subject of soft metrology has been launched.

### Introduction

Modeling is a common human activity. From an early age people have tried to represent objects by a model. A model is a system of postulates, data, and inferences presented as a simplified description of an entity or state of a process. The very act of making or understanding a model allows us to appreciate what is involved in the thing that is being modeled. Mathematical models also predict the future behavior of the system being considered. Because models are necessarily simplifications, ignoring certain details, we cannot be sure that we have included all the important factors involved. Running a simulation through a model and comparing the results with what might be expected to happen can tell us whether our model fairly represents the modeled object. Using the results of our simulation, we can go back and alter our model as necessary. There exist several definitions of what is modeling, for example: (1) modeling is to design, develop, explore, and evaluate models of real or imaginary situations, (2) modeling is a representation of some part or aspect of an object or system, which can be based in reality or imagination, (3) modeling is simulating in a simplified and

numerical way a real-world situation, and (4) modeling is the search for an analytical function or a procedure (model) that will give a specified  $n$ -variable output for any  $m$ -variable input. The third and fourth definitions concern mathematical modeling, which substitutes a real experiment by mathematical simulation.

Modeling on a computer is similar to other kinds of modeling except that the approach is more abstract and utilizes mathematics and logic. Computer modeling is the implementation of algorithms coded in computer programs to generate new information about the studied aspect of reality. Applications in analytical science span a wide range of approaches and methods that depend on the system studied. Some forms of modeling are covered explicitly in this Encyclopedia, for example, expert systems, or implicitly by the end use as in optimization.

### Basic Principles

In terms of the definition given above there are three steps in creating a computer model;

1. *To understand the real system in terms of the properties to be modeled.* Thus, one needs to have some background understanding of the modeled objects or processes. Their main features and their interrelation are evaluated. First, it consists of the selection of the influencing factors (input variables) and the outcome (output variables). Then, a mathematical model is constructed at an appropriate level. For example, atoms and molecules can be modeled

### Introduction

Modeling is a common human activity. From an early age people have tried to represent objects by a model. A model is a system of postulates, data, and inferences presented as a simplified description of an entity or state of a process. The very act of making or understanding a model allows us to appreciate what is involved in the thing that is being modeled. Mathematical models also predict the future behavior of the system being considered. Because models are necessarily simplifications, ignoring certain details, we cannot be sure that we have included all the important factors involved. Running a simulation through a model and comparing the results with what might be expected to happen can tell us whether our model fairly represents the modeled object. Using the results of our simulation, we can go back and alter our model as necessary. There exist several definitions of what is modeling, for example: (1) modeling is to design, develop, explore, and evaluate models of real or imaginary situations, (2) modeling is a representation of some part or aspect of an object or system, which can be based in reality or imagination, (3) modeling is simulating in a simplified and

numerical way a real-world situation, and (4) modeling is the search for an analytical function or a procedure (model) that will give a specified  $n$ -variable output for any  $m$ -variable input. The third and fourth definitions concern mathematical modeling, which substitutes a real experiment by mathematical simulation.

Modeling on a computer is similar to other kinds of modeling except that the approach is more abstract and utilizes mathematics and logic. Computer modeling is the implementation of algorithms coded in computer programs to generate new information about the studied aspect of reality. Applications in analytical science span a wide range of approaches and methods that depend on the system studied. Some forms of modeling are covered explicitly in this Encyclopedia, for example, expert systems, or implicitly by the end use as in optimization.

### Basic Principles

In terms of the definition given above there are three steps in creating a computer model;

1. *To understand the real system in terms of the properties to be modeled.* Thus, one needs to have some background understanding of the modeled objects or processes. Their main features and their interrelation are evaluated. First, it consists of the selection of the influencing factors (input variables) and the outcome (output variables). Then, a mathematical model is constructed at an appropriate level. For example, atoms and molecules can be modeled

by quantum mechanical or statistical mechanical equations. Equations such as Fick's laws of diffusion, the Navier–Stokes equation, rate equations, or equilibrium equations may be used to derive information about a system at a higher level. The model can only be as good as our understanding. The majority of failures of models stem from attempts to apply the resulting computer program to situations outside the range of applicability of the original model. While a theory has only the alternatives of being right or wrong, a model has a third possibility, namely that it may be right, but irrelevant.

2. *To develop an algorithm to describe the model.* The algorithm is defined as a detailed sequence of actions to accomplish some task. It is the procedure of implementing the model. This may include the solution of equations governing the system, compilation of rules in an expert system, and also the methods of input of data and output of results. It may be straightforward if the equation exists in a form from which the desired parameter can be explicitly calculated, or it may require the solution of nonlinear equations for a given variable, or the solution of differential equations (for example, Laplace's equation or rate equations). At the most basic level the model may simulate reality in a more direct way. For example, diffusion processes may be modeled by random walks. Here, particles move in a direction determined by the toss of a coin and in doing so implicitly solve Laplace's equation.

3. *To write a computer program to implement the algorithm.* In this step, the mathematical model is

converted into a computer model. This is usually a straightforward process but does require knowledge about the software used. It may be trivial, for example, to write a BASIC program to model the course of an acid–base titration, or it may result in programs that require hours of supercomputer time as in a molecular–dynamic simulation of liquid water. The required sophistication of the computer program depends on the complexity of the model and the constraints of the hardware and software. The code to perform the above-mentioned random walks calculation is simple and may be written in any high-level language. **Figure 1A** shows a computer model of a two-dimensional (2D) fractal created by allowing random walks (pixels on a computer screen) to move about until they hit and stick to the growth. A real growth of copper, electrodeposited from copper sulfate supported in filter paper, is shown in **Figure 1B**.

Computer modeling in analytical science takes a myriad of forms. **Table 1** brings together examples of the above principles for a range of models.

## Hardware and Software Considerations

When deciding to model a particular analytical problem thought must be given to the computer program and the platform on which it will run. While it is true that *ab initio* quantum mechanical packages exist to run on microcomputers, for serious work a

**Figure 1** Comparison between a simple random walk model of particle deposition and an electrochemically deposited copper fractal. (A) 2000 random walks on a square grid, (B) the digitized image ( $256 \times 256$  pixels) of copper electrodeposited from  $0.75 \text{ mol l}^{-1}$  copper sulfate and  $1 \text{ mol l}^{-1}$  sulfuric acid in an 11 cm Whatman 541 filter paper at 5 V. Both fractals are displayed using Lotus for Windows.

**Table 1** Computer modeling

<i>System</i>	<i>Model</i>	<i>Properties modeled</i>
Molecule	Quantum mechanical: <i>ab initio</i> , or empirical Force field model of interactions	Structure, electronic energy levels, thermodynamic data, analytical data, e.g., spectra, diffraction patterns, etc.
Clusters of molecules	Monte Carlo simulation Molecular dynamics Fluid mechanical equations	Structures of assemblies, dynamic evolution of structures, analytic data
Chemical reaction	Solution of rate equations Optimization for rate parameters	Concentration and related data (e.g., electrochemical current, temperature) with time
Industrial process	Solution of rate, diffusional, and hydrodynamic equations in space and time	Yields of product Optimal conditions to operate process (e.g., time, concentrations) Real-time process control
Analytical method	Expert system to model rules of configuration of method Optimization of method variables	Suggested conditions for given problem, e.g., mobile phase, column, and detector for ion chromatography
Analytical data	Multivariate analysis	Classification, calibration, pattern recognition
Instrument	Solution of equations governing operation of instrument given known inputs	Control of instrument Simulation of output of instrument Optimum design of new instruments

supercomputer running vectorized or parallel code is all but mandatory. The choice of hardware revolves about two factors, the amount of processing to be performed, which has a bearing on the speed of the machine, and the memory requirements of the task. The available computers range from microcomputers (personal computers, PCs) through workstations to minicomputers, mainframes, and supercomputers. Most computer modeling is performed on workstation computers. These have powerful processors combined with the flexibility and user-friendliness of microcomputer style user interfaces. The fast, high-quality graphics of workstations or the better microcomputers are of great use to the analytical scientist for presentation of results. Where speed and memory may be sacrificed for cheaper computing, microcomputers are useful, for example, in running instruments and in teaching. Desktop modeling of complex systems is changing the way we perform analytical science.

The advent of parallel computing also must be taken into account. It comprehends either using more than one computer, or a computer with more than one processor. For example, Dual Pentiums or Quad Pentiums may be used as a shared memory multiprocessor. Parallel and distributed computer systems support large-scale high-performance computing facilities.

If commercial software is available for a given simulation generally it should be purchased in preference to programs written in-house. At least the display of data, graphs, etc., and simple statistical manipulation should be performed by standard

routines. They can be found in large mathematical and statistical libraries, e.g., in the IMSL, NAG, or Netlib library, or the Numerical Recipes series of texts. The reasons for this advice are twofold. First, programmers employed by commercial houses are better than scientists at writing error-free, efficient, useable code. Second, the cost of writing commercial software is shared amongst all the purchasers.

Software written in a high-level language should be as portable as possible. Even if the code is intended for a single user, upgrading of a computer may render a program written in a dialect of a language specific to the earlier machine quite useless. Programming language is a formal language in which computer programs are written. The definition of a particular language consists of both syntax (how the various symbols of the language may be combined) and semantics (the meaning of the language constructs). Languages are classified as low level if they are close to machine code (the first and second generation) and high level if each language statement corresponds to many machine code instructions (starting from the third generation). There are five generations of computer languages: (1) First-generation languages (or 1GLs) are machine languages. (2) Second-generation languages (2GLs) generally consist of assembly languages. (3) Third-generation languages (3GLs) are high-level programming languages such as FORTRAN, BASIC, C and its successors, and Java. (4) Fourth-generation languages (4GLs) are closer to a human language since they use statements similar to it; they are commonly used in database programming, spreadsheets and scripts.

(5) Fifth-generation languages (5GLs) are used for artificial intelligence (AI) and contain visual tools to help develop a program. Good examples of the 5GLs are Visual Basic, Visual C++, and Delphi.

The 3GL of choice is C++, which is an object-oriented language, widely accepted, portable, and equipped by libraries of routines to extend the power of the basic language. It enables efficient and fast programming. However, in the chemistry- and analytical chemistry-oriented literature, many practical programs have been written in BASIC, FORTRAN, or PASCAL. The fourth generation includes macro languages written within applications such as databases and spreadsheets. Spreadsheet modeling is nowadays very popular even though it is useful only for relatively small systems. Lotus and MS Excel are the most popular spreadsheets, which include facilities to produce graphs, perform 'what if' calculations, solve equations, and to use simple statistical functions. In teaching analytical chemistry the student has a much better understanding of, for example, a pH titration if the form of the titration curve is displayed and the effects of changing concentrations and  $pK_a$ s may be viewed instantaneously. Spreadsheets are rather slow and cannot accommodate very large datasets, but within their limitations their use for chemical modeling is growing. Most spreadsheet applications are multidimensional, meaning that you can link one spreadsheet to another. A multidimensional spreadsheet, for example, is like a stack of spreadsheets all connected by formulas. A change made in one spreadsheet automatically affects other spreadsheets. Fifth-generation languages include declarative, list-based languages like LISP and PROLOG. The code of procedural 3GL informs the computer what to do with the data, e.g., 'loop round 10 times adding a number to a sum'. On the contrary, a declarative 5GL expresses what is true about a problem and then invites the compiler to engineer a solution that is logically correct. For example, a sorted list has the property that each succeeding number is greater than its predecessor, so that it can be used to implement a sort routine without DO loops in very few lines of code. Fifth-generation languages are at the heart of expert system shells because of their ability to handle logical data and the integration of code and data. Computers handle numbers and are optimized to manipulate numerical information. Among chemists and analytical chemists, the most popular 5GLs are MATLAB, MATHEMATICA, and MAPLE, as well as SAS (Statistical Analysis System) as a statistical language. The names of these languages are identical to the names of the software packages wherein they are used. MATLAB is both an intuitive language and a technical computing

environment. It provides core math and advanced graphic tools for data, analysis, visualization, and development of applications. MATHEMATICA is a list-based language, which combines techniques from procedural languages C/C++, and nontraditional languages. It is intelligent and ideal for AI applications enabling symbolic mathematical expressions much better than any human can, including integrals and derivatives. For example, by command  $D[\text{Log}[a-x]/4a^2, x]$  you can obtain the derivative of the first term in the square brackets according to  $x$  (the second term) with  $-a^2/4(a-x)$  at the output. If necessary, it is possible to simplify the result and/or make an evaluation for a given constant  $a$ . Lists are used mainly to represent vectors, matrices, tensors, sets, ranges of integrals and plots, as well as groups of arguments in functions. A common way to generate a list is with the Table command. An electro-analytical application of MATHEMATICA is described later.

## Model Architecture

The essential elements of any model are:

1. *Establishment of boundary conditions.* No model operates over all space and all time and so some limits must be specified. The integration of differential equations, whether explicitly analytical or numerical, requires limits to the integration (integration constants). The calculation of diffusion to an electrode requires the solution of Laplace's equation (Fick's laws). For this, the concentration of electroactive species at the electrode must be known in addition to how far into the solution the integration is to be made. In calculations involving time, conditions at zero time (and sometimes infinite time) are required. Optimization models generally require initial guesses and some knowledge of one state of the system (e.g., at zero time).
2. *The acquisition of input data.* Input data may be read from a file, generated in the model, or read from an experiment via analog-to-digital converters. It is these input data that distinguish one run of the model from another.
3. *Calculation of model output.* At the heart of a model simulation is the calculation itself. Usually this code is in a loop over time or distance. Considerable attention must be paid to the fitness of the model, both in terms of its underlying assumptions and its coding as a computer program. It must be understood that a model is not reality. Where the model deviates from reality must be known, and the computer realization of the model must not allow nonphysical behavior. For example, in fitting kinetic data rate constants cannot

be negative, even if the mathematical functions could be improved by allowing them to be so.

4. *Output of results.* The purpose of any model is to convey information about the real system. The results may be numbers output to file, printer, or screen; a visual presentation of the system such as the shape of a molecule, a graph of a property with time or space; or a voltage output via a digital-to-analog converter to control an instrument. The output of an expert system is advice on the problem.

## Examples of Modeling Techniques

### Molecular Structures and Processes

Molecular dynamics attempts to solve the dynamically evolving ensemble of molecules given the interactions between molecules. The form of the forces between molecules or atoms, the number of interactions (i.e., two- or three-body interactions), and the number of molecules that can be tackled by the program determine the success of the model. Molecular dynamics simulations can predict the internal energy, heat capacity, viscosity, and infrared spectrum of the studied compound and form an integral part in the determination and refinement of structures from X-ray crystallography or nuclear magnetic resonance (NMR) experiments.

Recent advances in commercially available software have concentrated on taking molecular modeling routines and embedding them in high-quality visualization packages with easy interfaces to libraries of molecules and programs that can predict the properties of the molecules created. The use of such packages in materials and drug design is relieving chemists of much wasted time in synthesis and analysis of compounds that are ultimately not suitable for the required task. Examples of modeling properties using computational instruments, that is, software that can predict the output of an analytical instrument applied to a compound, are X-ray diffraction (XRD), neutron and electron diffraction patterns, and high-resolution transmission electron microscope images. The chemist may make adjustments to a structure displayed on a computer screen and see the effect on, for example, the XRD of that compound in an adjacent window. Various three-dimensional (3D) graphics tools can be used for visualization of molecular structure. **Figure 2** shows a computer-generated 3D view of cyanocobalamin, vitamin B12. Databases of chemicals that contain 2D information of the structure of molecules in the form of connection tables may be used to generate 3D conformers. These structures may then be searched for specific properties such as ‘atoms of nitrogen and

**Figure 2** ORTEP 3 view of cyanocobalamin (vitamin B12) as created by POV-Ray 3D graphics tool. Crystal structure data were obtained from Cambridge Structural Database (CSD), code COVDEW01. (Courtesy of Moncol J and Koman M, Slovak University of Technology, Bratislava, Slovakia, with permission.)

oxygen separated by less than 0.5 nm each attached to an aromatic ring’. Candidate molecules are displayed or stored in a file for evaluation. In the pharmaceutical industry, the target molecular fragments are known as pharmacophores. If the interest is the interaction of a ligand at a receptor site and X-ray or NMR data are available for the site, then it is possible to model the interaction both in terms of the 3D shape and the forces between putative ligands and the site. Finally, the structure of a compound with the specified pharmacophore atoms at defined distances and angles is found and is used as the basis of a new drug.

### Dynamic Systems

Computer modeling of the kinetics of a reaction by solving rate equations is useful in the determination of mechanism and the estimation of rate parameters. Such analysis of kinetic data represents a higher-level approach to the problem of modeling than the molecular modeling discussed above. Here, we assume knowledge of the bulk properties of the system (the kinetic equations) and proceed to model the system comparing predictions to experimental measurements.

The problem is therefore to predict the concentrations of reactants and products with time given rate equations of the form:

$$\frac{dc_i}{dt} = \sum_j \kappa_j \prod_l c_l^{n_{lj}}$$

where  $c_i$  is the concentration of species  $i$ ,  $\kappa_j$  is the rate coefficient of the  $j$ th reaction ( $\kappa_j$  is the product of the

rate constant  $k_j$  and the number of molecules consumed or formed in the given reaction, e.g.,  $-1$ ,  $0$ ,  $+1$ , etc.) and  $n_l$  is the order with respect to species  $l$ . If no analytical solution exists for the set of equations, which is the case for all but the simplest systems, then they must be integrated numerically. When concentration data are available the solution of the rate equations is done as part of an optimization for the rate coefficients. At each guess of the  $\kappa_j$  values, the set of equations are integrated and the calculated concentrations are compared with measured values. If temperature also varies, as in a temperature-programmed desorption experiment, the rate constant  $k_j$  must be expressed in terms of the Arrhenius equation ( $k = A \exp(-E_a/RT)$ ) and the constants  $A$  and  $E_a$  determined.

In modeling kinetic data, it is important not to include more than the minimal set of reactions (rate constants). A sensitivity analysis that determines  $d \ln c_i / d \ln k_j$  for all  $i$  and  $j$  will show if a particular compound is superfluous (too small  $c_i$ ) or if a reaction is not required (too small  $k_j$ ). Kinetic modeling also highlights the fact that a model and the reality are not mirror images. A correct model should reproduce the desired facet of reality. A model that appears to give numbers that are in accord with reality is not necessarily correct. A simple example may be used to illustrate these points.

Adenosine 5'-triphosphate (ATP) hydrolyzes via the diphosphate (rate constant  $k_1$ ) and monophosphate ( $k_2$ ), or directly to the monophosphate with the pyrophosphate formation ( $k_3$ ). One mole of pyrophosphate then hydrolyzes to 2 mol of phosphate ( $k_4$ ):

Modeling of the two paths to fit phosphate concentration data by solving the rate equations in an optimization of the rate constants reveals that depending on the initial guess, two different, but apparently valid, results may be achieved. Figure 3 is the response surface of the optimization plotted as a function of the rate constants  $k_2$  and  $k_4$ . The response  $F(k)$  is defined as

$$F(k) = \left[ \sum_t (c_{t,\text{meas}} - c_{t,\text{calc}})^2 \right]^{1/2}$$

where  $k$  is the vector of rate constants,  $c_t$  is the concentration of phosphate at time  $t$ , and the subscripts 'meas' and 'calc' refer to the measured and calculated values, respectively.

**Figure 3** Response surface for the modeling of the hydrolysis of ATP as a function of two rate constants showing two minima A and B. T is the location of the true minimum. (Reproduced with permission from Hibbert DB and Sandall JPB (1989) Mechanism of the hydrolysis of adenosine 5'-triphosphate: A statistical evaluation of kinetic data. *Journal of Chemometrics* 3: 569–577; © John Wiley & Sons Ltd.)

Small values of the function (valleys) indicate good agreement between experiment and the model. The points labeled A and B are about equally good fits, but predict quite different mechanisms. To distinguish between the mechanisms pyrophosphate must also be measured. Visualization of data, in this case of the response surface in Figure 3, is a great aid in understanding the underlying processes when modeling.

Electrochemical systems lend themselves to modeling. In cyclic voltammetry, the peaks arise through a complex interplay of electrochemistry, solution chemistry, and diffusion, which influence the shapes of the voltammetric signals. Using microcomputers with sufficient power, the numerical solution of the relevant dynamic equations not only can confirm the mechanism, but good estimates of rate and diffusion coefficients can be obtained in real time. Several general simulation programs (e.g., DigiSim, ELSIM), libraries, and expert systems have been developed that bring the power of computer experiments to every electrochemist. One of the main tasks of computational electrochemistry is numerical modeling of electrochemical systems.

Many internal mathematical functions, available in mathematical software packages, are based on infinite series computations, optimized by a team of programmers, so that they are highly accurate for all practically used argument values. This has enabled to find, among numerous built-in functions of MATHEMATICA, those which can advantageously be used directly, or with adaptation, for calculations in linear

sweep voltammetry, thus creating an alternative way of computing the signal of this method. For example, the current–potential curve for a reversible electrode process can be calculated by means of the polylogarithm function  $\text{PolyLog}[n, z]$ , defined in MATHEMATICA as

$$\text{PolyLog}[n, z] = \sum_{k=1}^{\infty} z^k / k^n$$

Figure 4 shows the calculations of a single current output, a current–potential table (containing merely three output lines for the sake of space), as well as the corresponding plot, which are elegantly performable with only a few lines of instructions. The tables and plots for catalytic reaction with reversible charge transfer can be modeled with similar ease by

implementing the three-parameter transcendent ‘Lerch function’.

### Classification of Analytical Data

In linear multivariate data analysis (MDA) of a set of analytical data, the most common model is that linear relationships exist within the data that can be revealed, for example, in the principal components analysis (PCA) or linear discriminant analysis (LDA). Analytical data may represent the analyte concentrations of the multicomponent mixture, a spectrum of any kind, the results of clinical laboratory tests, the status of a technological process at a given time, etc. The classification of the investigated objects by the MDA techniques is an important task, which provides interpretation of complex problems, often

existing beyond the borders of Analytical Chemistry. However, it should be done by analytical chemists, not only due to its feedback to analytical measurements, but also to enhance their role from service to knowledge. For example, the models created by the MDA methods enable authentication of wines, their classification, and characterization according to the variety, vintage, or the producer. Moreover, based on sensory data from experts, wine samples may be classified into two or three classes according to sensorial quality. By analysis of the variables maximally influencing the discrimination of classes, which can be found that the chemical compounds have the largest impact upon the sensorial quality, i.e., the total taste, color, transparency, bouquet, and flavor. **Figure 5** shows the discrimination of white varietal wines (Gruener Veltliner, Mueller Thurgau, and Welsch Riesling) obtained from five producers during three consecutive vintages. Based on the gas chromatography–mass spectrometry analysis of volatile species influencing the wine aroma, the LDA enabled a very reasonable classification of wines by vintages. Nineteen variables (concentrations of volatile compounds) were finally used, among them six alcohols, five esters, seven terpenes, and one aliphatic acid. The variables

most influencing classification according to variety, vintage, producer, and sensorial quality were found. For solving different types of practical problems, the MDA methods use the same algorithms, processing the matrix of analytical data with objects in the rows and variables in the columns.

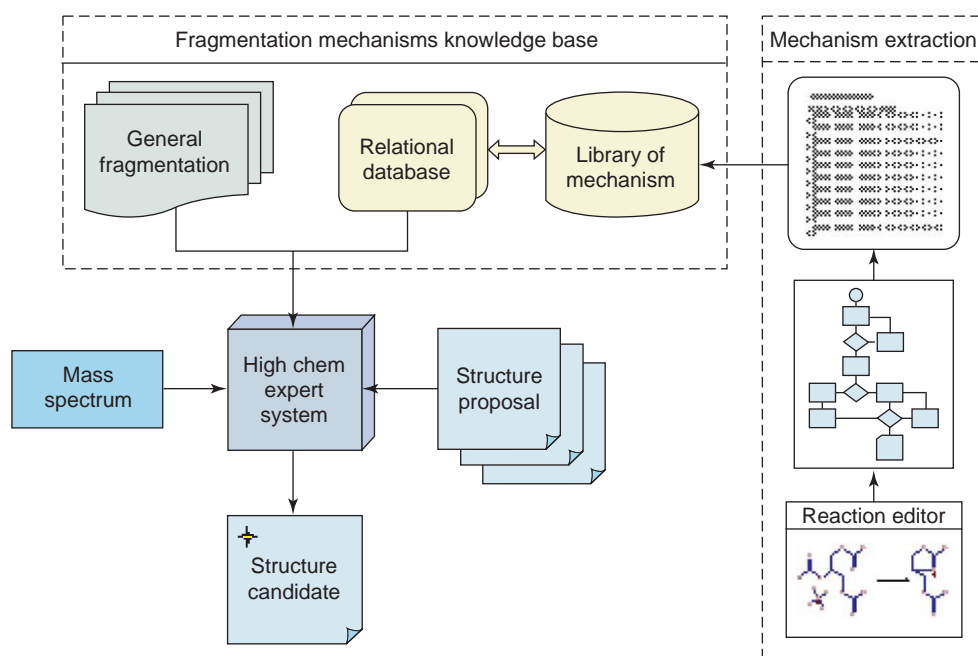

### Instruments

Many modern analytical instruments may be classed as virtual. They have no knobs or switches, but are run entirely from a microcomputer, the screen of which serves as the control panel of the instrument. The computer thus models the instrument and in doing so controls the real thing. In the virtual instrument approach the boundary between analog and digital information is pushed far towards the physical processes being measured. Lying at this boundary, analog-to-digital and digital-to-analog converters convert potentials to binary numbers, and vice versa, binary numbers from the computer are converted to potentials or currents that control the instrument's operation. The key advantage is that the specialized and costly 'analog processors' can be largely replaced by a powerful microcomputer with the specialized tasks being performed digitally under software control. It is now possible to build, rebuild, and modify virtual instruments in software without having to change the more expensive and less flexible hardware. The virtual approach also helps with complex analytical instruments in which many functions must be controlled simultaneously with a high degree of precision. Automation of repetitious tasks, as may be found in a clinical or forensic laboratory dealing with hundreds of samples, is made simpler by computer control. Use of a robot requires a model of the tasks to be developed in the controlling computer.

The process of modeling may be taken one step further in the development of new instrumentation. Modeling the output of a would-be instrument may save time and money in a trial and error attempt to refine parameters of its operation. An extension of the virtual instrument concept is the addition of artificial intelligence to the choice of parameters. **Figure 6** shows the flow diagram of the system for interpreting mass spectra based on automated prediction of fragmentation and rearrangement pathways (which is based on library mechanisms) combined with a module that uses general fragmentation rules. An intelligent fragmentation mechanism knowledge base, incorporated in a computer system, is used to predict unimolecular decomposition reactions. The knowledge base is encapsulated in a relational database that, in turn, is encapsulated in software with a graphical user interface. The software

**Figure 5** Classification of 88 white wine samples of three varieties from five producers according to *vintage* by linear discriminant analysis – plot in the coordinates of two main discriminant functions (DF2 versus DF1) composed of 19 original variables (concentrations of volatile, aroma creating compounds). Explanation of symbols: ○ denote the 1996 samples, × the 1997 samples, + the 1998 samples. Probability ellipses express the 95% probability level. **Figure 6** The flow diagram of the system of interpreting mass spectra based on a combination of a fragmentation mechanism database and general fragmentation rules. A mechanistic rationale that accounts for the fragmentation is algorithmically extracted from the reaction drawing. (Courtesy of R. Mistrik, HighChem, Ltd., Bratislava, Slovakia, with permission.)

contains an expert system that automatically extracts the decomposition mechanism for each given fragmentation reaction and determines the compound class range that the mechanism can be applied to. This approach is highly selective, which assures that skeletal and charge-remote rearrangements, ring closures and expansions, as well as compound specific mechanisms are applied to an appropriate structure. It allows the application of database mechanisms to a user-supplied structure and automatically proposes fragmentation reactions for the given compound. Each proposed fragmentation step is connected to its template mechanism, which allows the source and original database entry used for the prediction to be reviewed.

The synergy of two applied techniques, based on different principles, provides a powerful method of interpretation of mass spectra even when complicated rearrangements occur in the overall dissociation process. This approach considerably increases the success rate when matching spectral peaks with generated fragments.

Contemporary instruments are increasingly equipped with software systems that combine computer control of the measurements with elements of the simulation and data analysis. We are not far from seeing instruments that will carry out scientific investigations, not just measurements.

This article is reproduced from the previous edition, pp. 834–842, © 1995, Elsevier Ltd., with an updated Further Reading list supplied by the Editor.

### Introduction

Conductimetry (the measurement of conductivity) is a physical chemical measurement that provides information about the total ionic content of aqueous solutions. Using conductimetric techniques, electrolytic properties of ions such as diffusion, transport, mobility, and migration have been extensively studied and reported. Dissociation and dielectric constants of compounds have similarly been the subject of these physical chemistry studies in both aqueous and nonaqueous solutions.

Analytical chemistry has found great utility in conductimetric measurements in spite of its apparent nonspecificity. Rapid quantitative accuracy of a few tenths of a percent may be quickly accomplished by direct conductimetric determination of binary electrolytic solutions such as aqueous acids, bases, or salts. A nearly linear increase in conductivity is observed for solutions containing as much as 20% of solute. The concentration of strong solutions, such as the salinity of seawater, may be determined from conductance measurements; traces of electrolyte impurities, such as the impurity in ultrapure water, may be reported at the  $\mu\text{g l}^{-1}$  level. Conductimetric titrations may increase the accuracy of endpoint detection and permit titrimetric analysis of weak electrolytes, such as boric acid, which is not feasible by potentiometric or colorimetric

detection methods. Continuous monitoring of the progress of electrolytic chemical reactions and of industrial chemical streams may be done with cost-effectiveness, accuracy, and reliability exceeding those of many other 'online' analytical methods.

### Fundamentals

The electrical resistance of a solution is denoted by  $R$ ; its units are ohms which are commonly indicated by the Greek letter omega,  $\Omega$ . The electrical conductance is the reciprocal of the resistance; it may be given the symbol  $L$  and has the SI units of siemens (S) or the older units of reciprocal ohms (mhos) and the symbol  $\Omega^{-1}$ . Their relation is

$$L = 1/R \quad [1]$$

The resistance of a material is a property of its composition and geometry. For liquid samples, which are the subject of this article, a conductivity cell may be visualized as shown in **Figure 1**, where the area  $A$  of each of the parallel electrodes is  $1\text{ cm}^2$  and they are separated from each other by the distance  $d$  of 1 cm. The specific resistance, also called the resistivity, is characteristic of the solution material and concentration. It is denoted by the symbol  $\rho$ , has the units of ohm-centimeters and is defined by

$$\rho = R(A/d) = R/\theta \quad [2]$$

where  $\theta$  is the cell constant, useful for characterization of conductivity cells, with units of  $\text{cm}^{-1}$ :

$$\theta = d/A \quad [3]$$

The specific conductance, also called the conductivity, of the solution is denoted by the symbol

### Introduction

Conductimetry (the measurement of conductivity) is a physical chemical measurement that provides information about the total ionic content of aqueous solutions. Using conductimetric techniques, electrolytic properties of ions such as diffusion, transport, mobility, and migration have been extensively studied and reported. Dissociation and dielectric constants of compounds have similarly been the subject of these physical chemistry studies in both aqueous and nonaqueous solutions.

Analytical chemistry has found great utility in conductimetric measurements in spite of its apparent nonspecificity. Rapid quantitative accuracy of a few tenths of a percent may be quickly accomplished by direct conductimetric determination of binary electrolytic solutions such as aqueous acids, bases, or salts. A nearly linear increase in conductivity is observed for solutions containing as much as 20% of solute. The concentration of strong solutions, such as the salinity of seawater, may be determined from conductance measurements; traces of electrolyte impurities, such as the impurity in ultrapure water, may be reported at the  $\mu\text{g l}^{-1}$  level. Conductimetric titrations may increase the accuracy of endpoint detection and permit titrimetric analysis of weak electrolytes, such as boric acid, which is not feasible by potentiometric or colorimetric

detection methods. Continuous monitoring of the progress of electrolytic chemical reactions and of industrial chemical streams may be done with cost-effectiveness, accuracy, and reliability exceeding those of many other 'online' analytical methods.

### Fundamentals

The electrical resistance of a solution is denoted by  $R$ ; its units are ohms which are commonly indicated by the Greek letter omega,  $\Omega$ . The electrical conductance is the reciprocal of the resistance; it may be given the symbol  $L$  and has the SI units of siemens (S) or the older units of reciprocal ohms (mhos) and the symbol  $\Omega^{-1}$ . Their relation is

$$L = 1/R \quad [1]$$

The resistance of a material is a property of its composition and geometry. For liquid samples, which are the subject of this article, a conductivity cell may be visualized as shown in **Figure 1**, where the area  $A$  of each of the parallel electrodes is  $1\text{ cm}^2$  and they are separated from each other by the distance  $d$  of 1 cm. The specific resistance, also called the resistivity, is characteristic of the solution material and concentration. It is denoted by the symbol  $\rho$ , has the units of ohm-centimeters and is defined by

$$\rho = R(A/d) = R/\theta \quad [2]$$

where  $\theta$  is the cell constant, useful for characterization of conductivity cells, with units of  $\text{cm}^{-1}$ :

$$\theta = d/A \quad [3]$$

The specific conductance, also called the conductivity, of the solution is denoted by the symbol

**Figure 1** Principle of conductivity cell with contacting electrodes and recommended cell constant of  $1 \text{ cm}^{-1}$ .

$\kappa$  and is related to the above quantities by

$$\kappa = 1/\rho = L\theta \quad [4]$$

Actual electrodes are usually not planar and parallel. Cell constants  $\theta$  are most accurately determined by use of eqn [4] after measurement in standard reference solutions of known conductivities rather than by dimensional measurements of electrodes. Table 1 lists some of these standard solutions.

## Electrolyte Theory

The conductivity of a pure solution is given by the summation

$$\kappa = 10^{-3} \sum_i z_i C_i \lambda_i \quad [5]$$

**Table 1** Reference solutions for calibration of cell constants

Approximate concentration ( $\text{mol l}^{-1}$ )	Method of preparation	Temperature ( $^{\circ}\text{C}$ )	$\kappa$ ( $\mu\text{S cm}^{-1}$ )

<sup>a</sup>For ions of charge  $z$ , the figures given are on an equivalent basis, that is, they apply to the fraction  $(1/z)$  of a mole.

<sup>b</sup>The temperature coefficient, when known, is given as  $(1/\lambda_0)(d\lambda_0/dT)$ , with the units  $\text{K}^{-1}$ .

From Frankenthal RP (1963) In: Meites L (ed.) *Handbook of Analytical Chemistry*, pp. 5–30. New York: McGraw-Hill.

where  $z_i$  represents the charge of the  $i$ th ion,  $C_i$  its equivalent concentration, and  $\lambda_i$  its equivalent ionic conductivity. It is also useful to define the equivalent conductivity  $\Lambda$ , with the units  $\text{S cm}^2 \text{ mol}^{-1}$ :

$$\Lambda = \sum (\lambda_+ \lambda_-) = 1000 \kappa / C \quad [6]$$

The ionic conductance  $\lambda_i$  gives quantitative information about the contribution of each ionic species to the conductance of the solution. Its value is somewhat dependent on the total ionic concentration (denoted by the ionic strength  $\sum z_i C_i$ ) of the solution and increases with increasing dilution. It is convenient to tabulate numerical values of  $\lambda_0$ , the limiting value of  $\lambda$  as the concentration approaches zero (infinite dilution). Representative values of  $\lambda_0$  are given in Table 2. For many common acids, bases, and salts, values of the equivalent conductivity at infinite dilution and at real concentrations are given in Table 3.

Physical-chemical data concerning ionic equilibria can be obtained from conductimetric studies. Conductimetric measurement has led to the determination of acid and base dissociation constants, stability constants, and solubility product constants. Further details may be found in modern texts of physical chemistry.

## Instrumentation

Two types of conductance measurement systems are in use, employing either contacting or electrodeless principles. The most widely used method utilizes either two or four contacting electrodes immersed in the solution to be studied. A pair of contacting electrodes is commonly employed but their surfaces may become contaminated, adding spurious resistance to the circuit. Owing to the increased tolerance for fouling coatings, four-electrode conductivity is becoming available and popular.

The second type of conductance measurement utilizes noncontacting sensors and depends on inductive or capacitive effects to measure conductance.

## Contacting Electrode Methodology

Figure 2 illustrates several cells with contacting electrodes. Cell designs are available for a variety of research, routine, and industrial applications. Routine measurements use conductivity cells of suitable size that may be directly immersed in beakers, flasks, etc. Water analysis and online industrial measurements may require immersion or flow-through cells for continuous monitoring. Precision measurements

require that samples be contained within the conductivity cell, which may then be inserted in a constant-temperature bath, since the conductance of most solutions increases with the temperature at the rate of  $\sim 2\%$  per kelvin (cf. Table 2). Cells are available with built-in temperature sensors and associated instrumentation that computes automatic temperature compensation. Cells are made with various cell constants to accommodate solutions over wide ranges of conductances. Constants of 50, 10, 1.0, 0.1, and  $0.01\text{ cm}^{-1}$  are most widely used. Table 4 shows cell constants recommended for various ranges of conductance.

Electrodes are commonly made of platinum, although other noble or passive metals may be used including gold, silver, titanium, monel, stainless steel, and tungsten. The nonmetal graphite is also used because it is inexpensive, inert, and conductive.

Platinum electrodes may be coated with platinum black ('platinized') to increase the surface area and sensitivity. This finely divided form of platinum is prepared by electrolysis in a chloroplatinic acid solution containing a small amount of lead acetate. Platinization of platinum cells is not recommended on cells for measurements below  $10\text{ }\mu\text{S cm}^{-1}$ , although a trace of platinum black is sometimes suggested in these regions.

#### Circuit Considerations with Contacting Electrodes

Measurement of conductance, which is a measurement of the reciprocal of resistance, is done with a Wheatstone bridge such as that shown in Figure 3. In its traditional form, the bridge consists of four resistances, the unknown cell resistance  $R_C$  and three precision variable resistances,  $R_1$ ,  $R_2$ , and  $R_3$ , which are manipulated to show zero voltage drop across BD as observed by the null detector ND. Calculation of the unknown resistance is then derived from Ohm's law, where  $V$  is the voltage and  $I$  the electrical current across a resistance  $R$ :

$$V = IR \quad [7]$$

$$R_C = R_1(R_3/R_2) \quad [8]$$

If the voltage source used were direct current, chemical reactions might occur and deposits or gases evolving at the electrodes would change the electrical resistance. This effect, known as 'polarization' of the

**Figure 3** Wheatstone bridge for measuring conductance. (From Sawyer DT, Heineman WR, and Beebe JM (1984) *Chemistry Experiments for Instrumental Methods*, p. 61. New York: Wiley, with permission.)

electrodes, is eliminated by using alternating current as the voltage source to drive the bridge. However, the introduction of alternating current introduces a new set of measurement problems of its own. Instead of Ohm's law as in eqn [7], the voltage is governed by the alternating current impedance,  $Z$ :

$$V = IZ \quad [9]$$

The impedance now depends on three new variables: the frequency, inductance, and capacitance. The impedance,  $Z$ , in ohms, is given by equations such as

$$Z = (R_2 + X_2)^{1/2} \quad [10]$$

$$X = X_L - X_C \quad [11]$$

$$X_L = 2\pi fL \quad [12]$$

$$X_C = 1/(2\pi fC) \quad [13]$$

where  $R$  is the solution resistance in ohms as before,  $X_L$  is the inductive reactance in ohms,  $L$  is the inductance in henrys,  $X_C$  is the capacitive reactance in ohms,  $C$  is the capacitance in farads, and  $f$  is the frequency in hertz.

Driven by the alternating current, the conductivity cell now has capacitances between the electrodes, across the double layer presented by the solution-electrode interface and between the wires of the connecting cable. Additional resistances and inductances in the wire leads and connections further complicate

**Figure 4** Digital conductivity meter. (Courtesy of Thermo Electron Corporation, Boston, USA, used by permission.)

the construction of an accurate measuring circuit. Conductivity measuring circuits may have variable frequency sources ranging from 60 to 50 000 Hz. Low conductivity measurements made with small cell constants favor the lower frequency region. Modern conductivity instrumentation minimizes these sources of error by an appropriate combination of alternating current voltage and frequency, wave shape and sampling, and temperature compensation. A conductivity instrument with microprocessor, digital readout, and assorted conductivity cells is shown in **Figure 4**. Electronic instrumentation is available that automatically corrects for the cell constant and temperature and reads directly in terms of concentration of common electrolytes.

#### Four-Electrode Contacting Conductivity Cells

In many applications, electrodes become coated because of the characteristics of the measuring solution. A four-electrode technique that diminishes the effect of resistive electrode coatings is shown in **Figure 5**. Voltage from an alternating current source is applied to the two outer, current-carrying, electrodes in the same manner as the two-electrode measurement. The current,  $I$ , is a function of the sum of the solution and coating resistances. However, if two additional voltage measuring electrodes are introduced, such that the voltage across them is measured potentiometrically (with no current being withdrawn from the circuit by the measuring device), then the 'IR' drop of eqn [7] is measured only across the solution

**Figure 5** Principle of four-electrode conductivity measurement.

and is not affected by any resistive coating on the voltage measuring electrodes since no current is passing through this coating.

## Electrodeless (Noncontacting Methodology)

There are also two methods of conductance measurement that may be made without the electrodes in contact with solution. The first is a high-frequency method, frequently called oscillometry. The second is called 'electrodeless' or inductive conductivity.

### Oscillometry

Oscillometry employs high frequencies in the megahertz domain. Using a sample cell made of an

**Figure 6** (A) Inductance measuring oscillometric cell (From Pungor E (1965) *Oscillometry and Conductometry*. London: Pergamon, with permission). (B) Capacitance measuring oscillometric cell.

electrically insulating material such as glass or ceramic, the measuring cells can be classified as either capacitive or inductive. **Figure 6A** illustrates inductance high-frequency measuring cells and **Figure 6B** a capacitance cell. Special high-frequency circuits are associated with these measurements and extensive applications, paralleling those of classical conductimetry, have been reported using oscillometric techniques. Because of the complexity of interpretation, the observed data differ from those obtained with low-frequency methods. Measurements reported by oscillometry do not appear to have the exactitude of interpretation corresponding to conventional conductimetry. Commercial apparatus is of limited availability. An excellent and extensive monograph has been written by Pungor (see Further Reading), who has pioneered the work in this field.

### Electrodeless (Inductive) Conductivity

A method of measuring conductance without the use of contacting electrodes is applied for continuous and reliable measurement in the chemical process industries. A probe consisting of two encapsulated toroids in close proximity to each other is shown in **Figure 7**. This sensing unit, contained within non-conducting material such as glass, fluorocarbon, or other high-temperature resistant thermoplastic

**Figure 7** Principle of the electrodeless conductivity cell and instrument. (From Light TS and Ewing GW (1990) *Measurement of electrolytic conductance*. In: Ewing GW (ed.) *Analytical Instrumentation Handbook*, pp. 641–658. New York: Dekker.)

material, is totally immersed in the electrolytic solution. Precipitates or coatings adhering to this probe have little or no effect on the measured conductance. The input toroid generates a low-frequency electric field. An alternating current is induced in the solution and sensed by the output toroid as shown in **Figure 8**. The equivalent electrical circuit may be compared to a transformer with the toroids forming the primary and secondary windings, and the core replaced by a loop formed by the conducting solution. A configuration in which the probe does not come in contact with the solution is also possible and is illustrated in **Figure 9**. Here, the toroidal unit is installed around a section of nonconductive pipe containing the test solution. A complete current loop must exist for this arrangement to function.

In either case, the generating toroid is energized from a source of a stable ultrasonic frequency, typically 20–50 kHz. The pickup toroid is connected to a receiving circuit that measures the current induced through the secondary winding. The current is then amplified and displayed on a meter or transmitted to a strip chart recorder or computer. The output is a

**Figure 8** Representation of an electrodeless conductivity measuring circuit. (From Light TS and Ewing GW (1990) *Measurement of electrolytic conductance*. In: Ewing GW (ed.) *Analytical Instrumentation Handbook*, pp. 641–658. New York: Dekker.)

**Figure 9** Electrodeless conductivity cell mounted externally to a nonconducting pipe. (From Light TS and Ewing GW (1990) *Measurement of electrolytic conductance*. In: Ewing GW (ed.) *Analytical Instrumentation Handbook*, pp. 641–658. New York: Dekker.)

direct function of the conductance of the solution loop, and is interpreted in a manner analogous to the traditional measurement with contacting electrodes.

Commercially available instruments, one of which is shown in **Figure 10**, have useful ranges extending from  $50 \mu\text{S cm}^{-1}$  to  $2 \text{ S cm}^{-1}$ , with relative accuracy of a few tenths of a percent of full-scale, after-temperature compensation. A temperature sensor is incorporated in the toroid probe, and a compensation circuit corrects readings to the standard reference temperature of  $25^\circ\text{C}$ .

The electrodeless conductivity technique is used mainly in the chemical process industries for continuous monitoring where its freedom from maintenance is superior to contacting techniques. The smallest electrodeless probe is  $\sim 3.6 \text{ cm}$  diameter,

has an equivalent cell constant of  $2.5 \text{ cm}^{-1}$ , and requires a minimum solution volume of several hundred milliliters to ensure a complete solution loop without wall effects that distort the apparent cell constant. For the lower conductivity ranges, which require a smaller cell constant (cf. Table 4), the diameter of the probe must increase, and accurate

measurement below  $\sim 10 \mu\text{S cm}^{-1}$  is not practical. The relatively large probe and sample size have hindered applications for laboratory use.

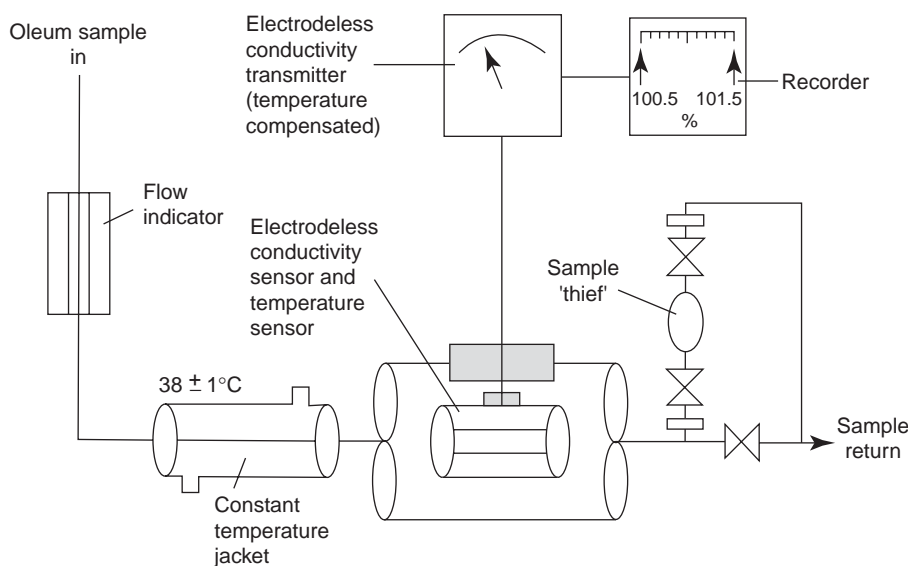

Numerous applications of electrodeless conductivity sensors have been published for the chemical, pulp and paper, aluminum, mining, and food industries. Similar instrumentation has been used for *in situ* measurements of the salinity of seawater. An instrument for continuous analysis of oleum in the range of 100–102% equivalent sulfuric acid, with an accuracy of 0.01%, is illustrated in Figure 11. A historical review has been published by Light (see Further Reading).

## Applications

Specific conductance and resistance values for a number of solutions are shown in Figure 12. Water itself is a very poor conductor. Its specific conductance due to dissociation into  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  ions is  $0.0550 \mu\text{S cm}^{-1}$  (resistivity of  $18.18 \text{ M}\Omega \text{ cm}$ ) at  $25^\circ\text{C}$ . Water of this theoretical purity is produced using commercially available nuclear-grade ion exchange resins. It is used extensively in the semiconductor, power, and pharmaceutical industries, and has replaced distilled water for general laboratory use. The conductivity measurement is extremely sensitive to traces of ionic impurities. The presence of  $1 \mu\text{g l}^{-1}$  of sodium chloride will raise the conductivity to  $0.0571 \mu\text{S cm}^{-1}$  ( $17.5 \text{ M}\Omega \text{ cm}$ ) at  $25^\circ\text{C}$ . A good grade of distilled or deionized water in contact with air measures  $1 \mu\text{S cm}^{-1}$  or ( $1 \text{ M}\Omega \text{ cm}$ ) at  $25^\circ\text{C}$  and falls far short of the purity requirement of

many industries. The conductivity of water has a large temperature coefficient compared to salts, acids, and bases. **Table 5** shows the conductivity of water over the range of 0–100 $^{\circ}$ C.

Solutions of strong electrolytes show a nearly linear increase of conductance with concentration up to  $\sim$ 10–20 wt.%. At higher concentrations the conductance decreases again due to such interactions as complexation reactions, formation of dimers, or higher polymers and increased viscosity. **Figure 13** shows the relation between conductivity and concentration for a few representative substances.

Conductometric titrimetry is widely applicable for titration reactions involving ions. **Figure 14**

**Figure 13** Conductivity–concentration curves for selected electrolytes. (From Ewing GW (1985) *Instrumental Methods of Chemical Analysis*, 5th edn., p. 337. New York: McGraw-Hill.)

demonstrates curves that result from titration of acids with sodium hydroxide. Graduations of acids, ranging from strong to very weak, are shown. Curve 1 represents a strong acid such as hydrochloric acid. As additions of sodium hydroxide are made, the conductance decreases until the equivalence point is reached. The point at which the slope changes defines the endpoint. For progressively weaker acids, such as dichloroacetic, monochloroacetic, or acetic acid, curves 2–4 represent the progress of titration. Unlike potentiometric or visual indicator methods, conductometric titrations do not require exact data in the vicinity of the endpoint. Extrapolation of the

**Figure 14** Conductometric titration curves of various acids by sodium hydroxide. Curve 1 represents a strong acid, and curve 5 an extremely weak one, while the others are intermediate. The acids are (1) hydrochloric acid, (2) dichloroacetic acid, (3) monochloroacetic acid, (4) acetic acid, and (5) boric acid. (From Ewing GW (1985) *Instrumental Methods of Chemical Analysis*, 5th edn., p. 337. New York: McGraw-Hill.)

data obtained before and after the slope change determines the endpoint. For titrations of very weak acids, such as curve 5 for boric acid, where the slope increases continuously, the endpoint cannot be detected by the usual potentiometric and visual methods. Using the slope change method of conductometric titrations, the endpoint may be determined by extrapolation.

Other types of titrations including those of mixtures of acids, precipitation titrations, such as silver with halides, and complex reactions are also adaptable to conductometric titration methods and frequently yield better analytical results than the

potentiometric or indicator methods. Analytical chemistry texts should be consulted for details of methodology.

Conductivity measurements are useful in following the reaction kinetics or diffusion processes when a change in ionic content or mobility is involved.

Ion chromatography using a conductivity detector has developed into one of the major instrumental tools. Ion chromatography fills a long-standing gap in analytical methods for anions by separating weak or strong ionic compounds on ion exchange columns followed by conductivity detection in a microcell.

## Introduction

The use of cosmetic products goes back thousands of years to antiquity; they were even found in some Egyptian graves. In the past, cosmetics were

considered as beautifying substances or preparations (e.g., lipstick, eye-shadow) that when applied to the face or the body would make us more attractive, whereas the term toiletries was sometimes reserved for those articles used in grooming (e.g., shampoo, deodorant) for washing or caring for the appearance. Nowadays, our perception of cosmetics has become more extensive and toiletries, perfumes, and other products have been included within the broad term 'cosmetics'. The cosmetic industry generates a lot of jobs and is an important source of income in the industrialized countries, as well as an indicator of prosperity.

This article deals with the different types of cosmetic formulations (including toiletries), forms and functions, analytes of interest, pretreatment and sample preparation, and analytical techniques. A thorough description of the main ingredients of toiletries – namely surfactants, is given in another article and due to their particular relevance and special characteristics, perfumes are also considered elsewhere.

## Definitions and Nomenclature

A cosmetic, according to the current European Union (EU) legislation, is any substance or preparation intended to be placed in contact with the various external parts of the human body (epidermis, hair system, nails, lips, and external genital organs) or with the teeth and mucous membranes of the oral cavity with a view exclusively or mainly to cleansing them, perfuming them, changing their appearance, and/or correcting body odors and/or protecting them or keeping them in good condition.

The US Food and Drug Administration (FDA) defines cosmetics by their intended use, as articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into or, otherwise, applied to the human body for cleansing, beautifying, promoting attractiveness, or altering the appearance.

Different laws and regulations apply to cosmetics and drugs. However, some products meet both definitions. This may happen when a product has two intended uses. Such products must comply with the requirements for both cosmetics and drugs. For example, an antidandruff treatment shampoo is a drug because one of its intended uses is to treat dandruff, but it is also a cosmetic because its other use is to clean hair. The same happens with toothpastes containing fluoride. Other products such as sunscreens are considered by EU legislation as cosmetics (they protect the external part of the human body) whereas they are considered as drugs by US legislation (the

protection function is not included in the definition of the FDA). The cosmetics industry uses the word cosmeceuticals to refer to those cosmetic products that have medicinal or drug-like benefits, although the legislation does not recognize this term.

Generally, the cosmetic ingredients are designated either by their chemical name or, preferentially by the simplest International Nomenclature Cosmetic Ingredient (INCI) to take into account the need for a truly international approach enabling comprehensive and short names for use in labeling.

## Types of Cosmetics: Cosmetic Forms

Cosmetic formulations are composed of active ingredients and excipients. Active ingredients are compounds directly related with the efficacy of the cosmetic product. Excipients can have different functions such as: to facilitate the preparation of the formulation, to achieve the required physicochemical properties, to improve the efficacy or to provide stability to the finished product. On the other hand, active ingredients in some cosmetic formulations can act as auxiliary ingredients in other formulations.

Different reasons determine the physical form chosen by the manufacturers for a cosmetic formulation, these may include: the solubility of the active ingredients, the type of skin, the adequate level of skin penetration according to the function of the cosmetic, or some commercial reasons such as comfort or the easiness of use.

**Table 1** shows the different types of cosmetics and their more common cosmetic forms.

## Efficacy and Safety: Analytes of Interest in Cosmetics Analysis

Cosmetic samples are often very complex. They may contain numerous ingredients, in a very wide range of concentrations and for diverse applications. The complexity of these samples ranges from just a few to 20 or more ingredients, which can be found in any given manufactured cosmetic.

The active ingredients or excipients included in cosmetic formulations have different functions (e.g., antioxidants, surfactants or emulsifying agents, preservatives).

**Table 2** shows the most important functions of cosmetic products (according to the EU) and some examples of compounds which can provide these properties to the cosmetics.

The analytes of main interest in cosmetic formulations are those related to the efficacy and safety of the products.

**Table 1** Types of cosmetic products and their most common formulation forms

<i>Cosmetic products</i>	<i>Most common formulation forms</i>
<i>General toilet products</i>	
After-bath powders, hygienic powders	Powder
Toilet soaps, deodorant soaps	Solid soap
Toilet waters, eau de Cologne	Lotion, water, spray, paper toilet
Bath and shower preparations	Salt, foam, oil, gel
Products for care of the teeth and mouth	Paste, gel, lotion
Products for external intimate hygiene	Gel, lotion, paper towel
Deodorants and antiperspirants	Stick, spray
<i>Depilatories and shaving products</i>	
Depilatories	Lotion, wax
Shaving products	Cream, foam, lotion
<i>Sun bronzing and whitening products</i>	
Sunscreens products	Cream, lotion, emulsion, spray
Products for tanning without sun	Cream, lotion, emulsion, spray
Skin-whitening products	Cream, lotion, emulsion
<i>Skin care products</i>	
Products for skin care of hands, face, feet, lips, body, etc.	Cream, emulsion, lotion, gel, oil, solutions, suspensions
Antiwrinkle products	Cream, lotion, emulsion, gel
Face masks (with the exception of chemical peeling products)	Paste, cream, gel
<i>Make-up and removing products</i>	
Products for making-up the face and the eyes	Powder, cream, suspension, past, pencil
Products for removing make-up from the face and eyes	Cream, gel, lotion, paper towel
Products intended for application to the lips	Stick, cream
Products for nails	Lotion, suspension
<i>Tinted bases and hair care products</i>	
Products for dying, bleaching, waving, straightening, fixing, setting, cleansing, conditioning, hairdressing products	Cream, lotion, oil, powder, shampoo, spray

The efficacy of a cosmetic product can be defined as the capacity to provide the desired effect. The safety of cosmetic products is of great importance because these products are used without medical supervision, on sensitive areas of the body and/or for long periods of time. The safety relates to composition, packaging, and information and responsibility

for all these aspects falls totally on the producer or the importer, who is responsible for any marketing liability. A rigorous control of the cosmetic product on the market is a key requirement in ensuring the protection of the consumer; therefore, quality control of the analytes of interest in the finished product is necessary to assure both the efficacy and the safety (Figure 1). The cosmetic industry requires simple, accurate and, if possible, green analytical methods that can be routinely and safely used in the quality control laboratories.

### Efficacy of the Finished Product

Active ingredients provide the efficacy of the cosmetic formulation to achieve the desired result with the aid of appropriate excipients. For example, the function of deodorants is to inhibit the growth of microorganisms which cause unpleasant odors; zinc salts of the rinoic acid, or triclosan (2,4,4'-trichloro-2'-hydroxydiphenyl ether) can be used as active ingredients. Antiperspirants have to reduce the secretion of the sweat glands, aluminum or zirconium salts can do this. Organic coloring compounds are used in hair dye formulations. Organic compounds whose molecules contain  $\pi$  electrons which absorb UV radiation can be used as filters in sunscreens, thus imitating melanine which prevents the human body from absorbing solar radiation naturally. As the active ingredients are directly related to the desired efficacy of the cosmetic, the determination of their concentration at production level has to be controlled.

Some ingredients can degrade with time or storage conditions and they must be specially controlled in order to ensure the efficacy of the cosmetic. In this sense, the expiry data must be indicated with the warning: 'Use preferably before...'. If necessary, the storage conditions should also be indicated. Moreover, if the useful life of the product is less than 30 months, EU legislation obliges the manufacturer to indicate the expiry date after the product has been opened.

### Safety of the Finished Product

There are official statements in each country that legislate about finished cosmetic products, for example: the Scientific Committee on Cosmetic Products and Non-Food Products (SCCNFP) or the EU Directorate General Health and Consumer Protection or the Center for Food Safety and Applied Nutrition (CFSAN) in the US FDA.

A large number of compounds are considered as potentially harmful for human health and their use as cosmetic ingredients (e.g., cadmium and its

**Table 2** Representative compounds included in the cosmetic formulations to achieve different functions

Function	Examples of compounds used in the cosmetic formulations
Abrasives	Silica, alumina, pumice, sodium silicoaluminate, zeolites
Absorbents	Cellulose, bismuth subnitrate, talc, magnesium carbonate
Additives	Acetaldehyde, acetaminophen, gallic acids
Anticorrosive	Nitromethane, sodium nitrite
Antidandruff	Zinc pyrithione, ketoconazole, piroctone olamine
Antifoaming	Isopropyl alcohol, hexyl alcohol, silica silylate, dimethicone
Antimicrobials	Benzoic acid, potassium iodide, zinc acetate, zinc borate, <i>p</i> -hydroxybenzoates
Antioxidants	Butylhydroxytoluene, citric acid and its salts, hydroquinone, ascorbic acid, tocopherol
Antiperspirant	Aluminum chlorhydrate, aluminum chloride, aluminum sulfate
Antistatic	Alanine, oleamine, lanolin, pyridoxine, aspartic acid
Binders	Agar, alginic acid, starch, PTFE, synthetic wax
Biological additives	Amylase, ovum, oyster ( <i>Ostrea edulis</i> ), collagen, colostrums, folic acid
Bleaching	Ammonium persulfate, hydroquinone, strontium dioxide
Botanicals	<i>Aloe barbadensis</i> , <i>Avena sativa</i> , <i>Castanea sativa</i> , <i>Coffea arabica</i>
Buffering	Phosphoric acid, citric acid, lactic acid, ethanolamine
Chelating	Oxalic acid, bismuth citrate, diisopropyl oxalate, EDTA
Cosmetic coloring	Inorganic and organic natural pigments, synthetic pigments
Denaturants	Acetone, ammonia, eucalyptol
Deodorant	Zinc gluconate, zinc glutamate, zinc ricinoleate, triclosan
Depilatory	Thioglycolic acid, potassium thioglycolate, zinc sulfide
Emollients	Propylene glycol citrate, cholesterol, dihexyl adipate, vegetable oils
Emulsifying	Triethanolamine, stearic acid, stearyl alcohol, sodium lauryl sulfate
Emulsion stabilizers	Aluminum dilinoleate, magnesium hydroxide stearate
Film formers	Acetyltributyl citrate, polyacrylamide, polyisobutene, starch, triacetin
Hair dyes products	Henna, resorcinol, thymol, silver nitrate, benzenic derivatives
Humectants	Glycerin, propylene glycol, sorbitol, glucose, fructose, glutamic acid
Opacifiers	Silica, cellulose, zinc carbonate, alumina
Oral care	Calcium carbonate, allantoin, aluminum fluoride, sodium monofluorophosphate, sodium fluorosilicate
Oxidizing	Potassium chlorate, potassium bromate, potassium persulfate
Preservatives	Ammonium sulfite, formaldehyde, propionic acid, formic acid
Propellants	Carbon dioxide, nitrogen, ethane, propane
Reducing	Thioglycolic acid, isooctyl thioglycolate, sodium hydrosulfite (sodium dithionite)
Solvents	Water, alcohol, glycerin, acetone, pentane, isobutyl acetate
Surfactants	Tridecylbenzenesulfonic acid, potassium lauryl sulfate, potassium myristate, potassium laurate
UV absorbers	Titanium oxide, benzophenones, PABA and derivatives, methoxycinnamates, salicylates
Viscosity	Polyacrylic acid, methylcellulose, zinc laurate, tin oxide, gelatin, paraffin, agar, alginate, betaine

**Figure 1** Relationship between both efficacy and safety of the cosmetics and production quality control.

compounds, hexachlorophene) is prohibited by the different legislations.

Other substances are subject to restrictions in concentration and/or field of application (e.g., after

toxicological evaluations on a large number of dyes, the SCCNFP indicates the parts of the body where they can be safely applied, the cosmetics containing them, the maximum concentration levels authorized and some specific warnings).

Some substances have special labeling instructions (e.g., FDA suggests that the labeling of a cosmetic product that contains an alpha hydroxy acid (AHA) and that is intended for topical application to the skin or mucous membrane should carry instructions that convey the following information: 'Sunburn Alert: This product contains an alpha hydroxy acid (AHA) that may increase your skin's sensitivity to the sun and particularly the possibility of sunburn. Use a sunscreen and limit sun exposure while using this product and for a week afterwards.'

These substances, therefore, present particular concerns related to the safety of the finished product.

Furthermore, routine analysis and quality control often requires the analysis of raw materials. For

instance, even though methyleugenol is naturally present in essential oils used as components in cosmetic products, the SCCNFP recommends that methyleugenol should not be intentionally added as a cosmetic ingredient, and the maximum authorized level in the finished product is legislated. Possible contaminants present in the raw materials must also be checked.

A cosmetic product must not cause damage to human health when applied under normal or reasonably foreseeable conditions of use. These products must not be harmful, either immediately (for example, by causing allergic reactions) or in the long term (for example, leading to cancer or natal defects).

Different bioassays using animals were used in the past to evaluate the safety and efficacy of finished products but nowadays, authorities encourage researchers to develop alternative *in vitro* methods that can substitute all the animal assays. The aim is both to avoid or to reduce the number of these experiments at the present time and to completely forbid them in the near future.

Studies on safety and efficacy are continuously being developed by researchers. The advances in some of these studies result in nocive ingredients being forbidden and substituted by others. Other studies are devoted to search for new ingredients to improve the efficacy of the formulations.

Cosmetic products should remain where they are most effective, that is on the skin surface; they should not penetrate into tissue. However, different *in vivo* and *in vitro* studies show that some cosmetic ingredients are absorbed through the skin. Due to this, the concern about the selection of cosmetic ingredients now includes the analysis of samples taken from cosmetic users such as urine, blood serum, nails, hair, etc (e.g., determination of parabens on the skin of human fingers, determination of organic UV filters in urine). The development of selective and sensitive analytical methods, which are capable of controlling the bioaccumulation and excretion mechanisms of these compounds, is interesting from the viewpoint of health. These studies will inform us about ingredients which do not filter through the skin and can therefore be safely applied.

## Preparation of Samples for Analysis

Sample treatment is a vital and time-consuming part of the analytical procedure, which contributes decisively to the accuracy and precision of the results. For these reasons, the search for the most suitable sample pretreatment is of great interest in the overall analysis.

Sample pretreatment in cosmetic analysis depends on the cosmetic form of the finished products and the analytes to be determined, and the analytical techniques to be used.

### Preparation for the Determination of Elements

The majority of the analytical techniques used for determining elements in cosmetic samples require the dissolution and dilution of samples in an appropriate solvent, with some exceptions such as X-ray fluorescence spectrometry or neutron activation analysis (NAA) which allow, in the case of solid samples, direct measurement. For example, iron and zinc have been determined in compact eye-shadow, face-powder, and rouge by NAA without prior treatment of samples.

However, most cosmetic samples require a pretreatment like complete acid digestion or leaching of the analytes, which may or may not be relatively difficult depending on how efficiently the analytes are extracted from the matrix. Microwave energy permits rapid heating of samples, which considerably reduces pretreatment time. For example, heavy metals have been determined in some cosmetics (lipsticks, powders) using different atomic spectroscopic techniques after acid treatment assisted by microwave irradiation.

Liposoluble samples such as creams or oils can be directly emulsified in water, with the aid of a surfactant, and some metallic elements can be determined by atomic spectrometric techniques without any pretreatment and using aqueous standards. For example, sunscreen creams have been emulsified and zinc (present as zinc oxide) determined by atomic absorption spectrometry.

### Preparation for the Determination of Organic Compounds

Some cosmetic samples, such as creams, emulsions, lotions, lipsticks, etc. can be directly dissolved by the appropriate solvent (e.g., methanol, acetonitrile, dimethylformamide, tetrahydrofuran, ethanol, or mixtures) with the aid of manual or ultrasonic agitation and analyzed by chromatography or related techniques. Sometimes, however, the sample needs cleaning up before chromatographic determination, especially when gas chromatography is involved.

Techniques such as liquid-liquid extraction are usually employed to improve the selectivity of analytical techniques and, specially, for removing the matrix (e.g., antimicrobial ingredients have been extracted from deodorant by liquid-liquid partition with n-hexane/H<sub>2</sub>O before gas chromatographic determination).

Analytes which are present in some difficult to dissolve samples, such as make-up formulations, can be separated from the solid matrix by leaching using the appropriate solvent (e.g., different UV filters have been leached from lipstick samples by ethanol with the aid of ultrasonic irradiation).

Other separation techniques such as solid-phase extraction (SPE) enable the selective retention and elution of both matrix and analytes (e.g., benzophenone-4 and phenylbenzimidazole sulfonic acid have been determined in sunscreen sprays by UV spectrometry using an online SPE sequential injection system).

Supercritical fluid extraction (SFE) has a very good field of application in cosmetics analysis as separation treatment before different analytical techniques (e.g., waxes, UV filters, preservatives, or vitamins have been extracted from different cosmetic matrices).

## Analytical Techniques

The number and varied chemical nature of the substances that make up cosmetics ingredients have lead to a great variety of methods for cosmetic analysis.

Classical noninstrumental methods are used in routine analysis due to their easily accessible laboratory equipment required for implementation. In addition, they are often the official methods proposed by the corresponding government commissions. Acid-base titrations are used for ingredients that present acid-base properties (e.g., potassium and/or sodium hydroxides), iodometric titrations for the determination of oxidizing agents (e.g., hydrogen peroxide in hair-care products); even gravimetric determinations are carried out (e.g., oxalic acid and/or its alkaline salts by precipitation with calcium or zinc by 8-hydroxyquinoline).

The use of modern instrumental techniques has increased over the last few years and a great number of scientific publications using different techniques (Figure 2) can be found in the cosmetic analysis literature. Chromatographic techniques are the most used because they allow the simultaneous determination of a number of components without the need for a laborious cleanup process.

### Chromatographic and Related Techniques

Classical thin-layer chromatography (TLC) allows identification and semiquantitative determination of multicomponents with very simple laboratory equipment (e.g., certain oxidation coloring in hair dyes by two-dimensional TLC, ionic surfactants in toiletries). This technique is often used as a previous separative step followed by an instrumental determination.

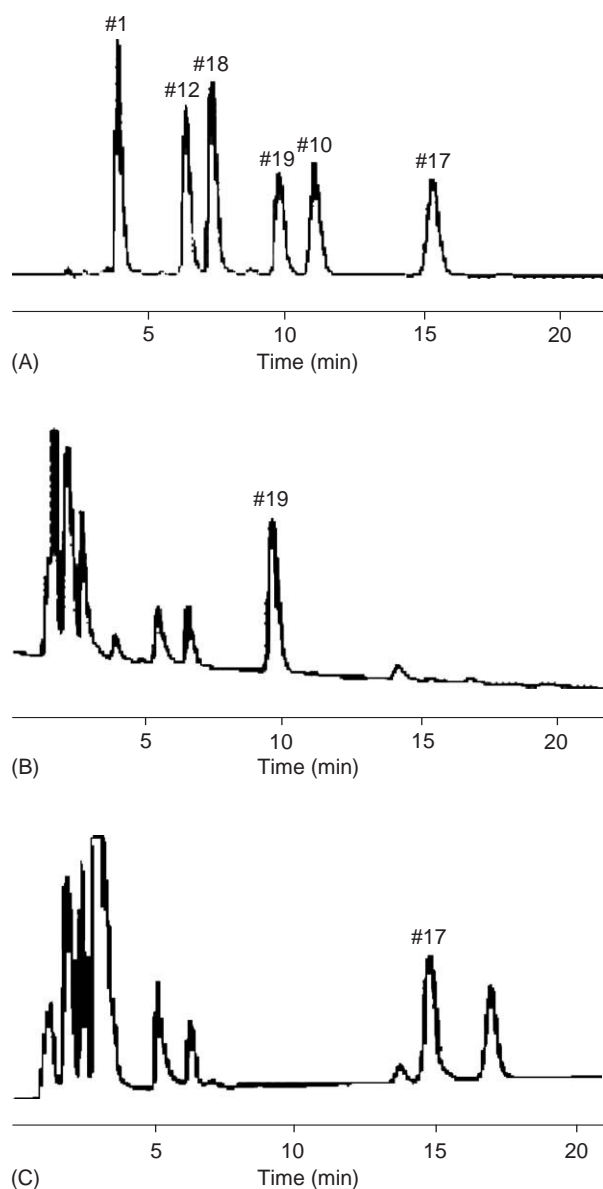

**Figure 2** Percentage distribution of analytical techniques used in cosmetics analysis. (Data obtained from the publications compiled in *Analytical Abstracts* before November 2003.)

High-performance thin-layer chromatography (HPTLC) presents better resolution, sensitivity, and precision than classical TLC, and allows determination of the analytes with sufficient accuracy (e.g., determination of preservatives in creams and lotions); besides this, sample preparation may be simple. However, due to the high versatility of other techniques, this is probably the less commonly used of the chromatographic techniques in this area.

Gas chromatography (GC) has a very good performance, but is limited to volatile and thermally stable analytes. Moreover, sample preparation is often more complex than required by other chromatographic techniques, laborious clean up and/or derivatization steps are generally necessary.

Liquid chromatography (LC) with UV detection is the most commonly used instrumental technique. Fluorescence and electrochemical detectors have also been used. The main advantage of this technique is its versatility. The great variety of separation mechanisms allows determination of any sort of analytes (e.g., anionic surfactants in toiletries by reverse phase ion-pair chromatography, ionic substances by ion-exchange chromatography, UV filters in sunscreens by reverse phase LC). Moreover, switching and multidimensional chromatographic techniques allow on-line sample pretreatment (cleanup, derivatization or trace enrichment) and increased resolution.

As mentioned before, pretreatment of cosmetic samples is often necessary before chromatographic determination. For instance, Figure 3 shows the chromatograms obtained from a solution containing some corticosteroids (forbidden by legislation) standards and from two extracts obtained from commercial cosmetic products. A previous screening of the samples using a TLC method to detect the presence of corticosteroids and a SPE cleanup pretreatment of samples was carried out before analysis. Figure 4 shows the chromatogram obtained in the determination of UV filters in a sunscreen lipstick purified by SFE.

**Figure 3** Chromatograms obtained from: (A) a standard solution containing hydrocortisone-21-acetate #1, betamethasone-17, 21-dipropionate #10, fluocinonide #12, betamethasone-17-valerate #18, and clobetasol propionate #19; (B) and (C) extracts from a shampoo and cream, respectively, obtained by solid-phase extraction. (Reproduced from Gagliardi L, de Orsi D, del Giudice MR, Gatta F, *et al.* (2002) *Analytica Chimica Acta* 457: 187–189.)

Electrophoretic techniques, mainly capillary zone electrophoresis (CZE) and also capillary isotachopheresis (ITP) or micellar electrokinetic chromatography (MEKC) have been used in cosmetic analysis (e.g., determination of cationic surfactants in toiletries, parabens in different cosmetics, fluoride, and polyphosphates in toothpaste, hair dyes, or acid preservatives in cosmetic lotions). However, their use is less extensive than LC, probably because the

**Figure 4** Chromatograms obtained from: (A) a standard mixture containing benzophenone-3 (2-hydroxy-4-methoxybenzophenone or oxybenzone) 1; octyl dimethyl PABA (2-ethylhexyl-*p*-dimethylaminobenzoate) 2; 4-methylbenzylidene camphor 3; octyl methoxycinnamate (2-ethylhexyl-*p*-methoxycinnamate) 4; butyl methoxydibenzoylmethane (4-*tert*-butyl-4'-methoxydibenzoylmethane) 5; (B) an extract from a lipstick, obtained by supercritical fluid extraction. (Reproduced from Scalia S (2000) *Journal of Chromatography A* 870: 199–205.)

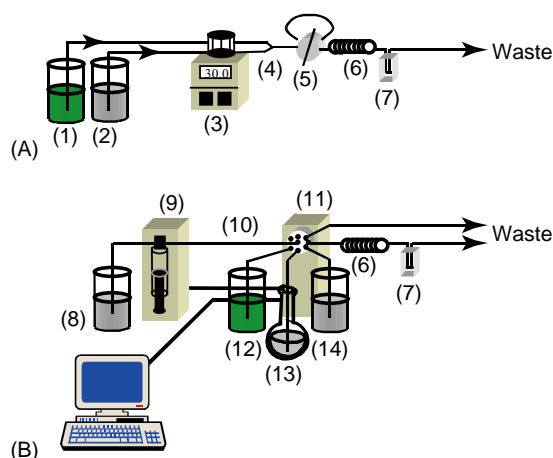

instrumentation is still not so general and moreover LC allows the determination of a great number of analytes whose concentration levels in cosmetic samples can be determined without difficulty.

Hyphenation between GC or LC and mass spectrometry (MS) has improved these techniques, however the high cost of the equipment limits its use in routine quality control. GC–MS has been used to determine different analytes in cosmetics (e.g., essential oils). LC–MS has also been used (e.g., ceramides, cationic and nonionic surfactants, preservatives).

### Molecular Spectrometry

Infrared spectroscopy (both IR and FTIR) has been used in some cases (e.g., anionic surfactants

**Figure 5** Flow injection systems used to determine benzophenone-3 (2-hydroxy-4-methoxybenzophenone or oxybenzone) in sunscreen creams: (A) flow injection analysis (FIA); (B) sequential injection analysis (SIA). Reagents (1), (2), (12), (14); peristaltic pump (3); merging point (4); injection valve (5); reaction coil (6); flow cell (7); ethanol (8); autoburette with syringe (9); holding coil (10); eight-channel selector valve (11); sample or standard solutions (13). determination in shampoos, methanol and ethanol in different cosmetics, glycolic and lactic acids in creams). The low selectivity of UV absorption spectrophotometry is its main disadvantage in this field, which makes inclusion of a cleanup step mandatory most times. Some colorimetric reactions have been proposed to determine different analytes of interest in cosmetics. Luminescence techniques have scarcely been used (e.g., determination of antioxidants or potential nitrosating agents).

Dynamic methods have been proposed for carrying out online UV spectrometric procedures to determine active ingredients such as UV filters in sunscreens, based either on selective SPE of the analytes or on derivatization reactions to obtain colored or chemiluminescent products. Figure 5 shows two flow systems used to determine benzophenone-3 in sunscreens without matrix interferences by reaction with Ni(II) in ammoniacal medium.

### Atomic Spectrometry

Atomic spectrometry has been used to determine metallic components in toothpaste, sunscreen, shampoos, cosmetic pigments, etc. Elements can be found in cosmetics and toiletries as active ingredients (e.g., Se in shampoos) or as impurities from the raw materials. The elements most frequently determined are Pb, Hg, and As; but Se, Cd, Zn, Ti, Fe, Cr, Sr, Bi, Ba,

Mn, Cu, or S have also been determined. Flame atomic absorption spectrometry and electrothermal atomic absorption spectrometry have been the most used techniques. Other techniques used to a lesser extent, are inductively coupled plasma-atomic emission spectrometry (e.g., selenium in shampoos) or atomic fluorescence spectrometry (e.g., determination of mercury by cold vapor).

### Other Techniques

Different analytes are determined by using electrochemical techniques such as differential pulse voltammetry (e.g., metal ions and chlorhexidine in oral care products, glycolic acid in creams, dyes in lipsticks) or potentiometry (e.g., inorganic compounds and anionic and cationic surfactants in personal care products). Modified carbon electrodes and biosensors have been developed to determine some cosmetic ingredients by techniques such as voltammetry or potentiometry.

Other analytical techniques have less frequently been used: nuclear magnetic resonance spectroscopy (NMR) (e.g., tocopherols in toothpaste by hyphenated LC–NMR), energy dispersive X-ray fluorescence (ED-XRF) (e.g., heavy metals determination), surface enhanced Raman scattering (e.g., determination of 4-aminobenzoic acid or PABA, in sunscreens), neutron activation analysis (e.g., determination of iron and zinc), and thermometric analysis (e.g., fluoride in toothpaste).

# COULOMETRY

P C Hauser, The University of Basel, Basel, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Coulometry is an electrochemical method in which the total charge (the number of coulombs) consumed in the redox conversion of an analyte at an electrode is measured. It is not to be confused with colorimetry, the spectroscopic method. Coulometry is distinguished from voltammetric and amperometric methods by not relying on mass transport current control to obtain a signal dependency on concentration. Coulometry is an absolute method, which means that calibration is generally not necessary as electrical charge can be measured with high accuracy. This is an advantage shared with gravimetry. A further advantage is its inherent simplicity and therefore limited expense. The method was very popular around the middle of the twentieth century but has been replaced in many applications by voltammetric methods such as differential pulse polarography or recent nonelectrochemical analytical methods such as high-performance liquid chromatography (HPLC). However, some applications are still current, most notably the important determination of water content by the Karl Fischer method. Interesting new developments with regard to miniaturization and sensitivity have also been reported.

## Fundamentals

The total charge passed between two electrodes in the redox reaction of an analyte is given by the Faraday equation:

$$Q(t) = \int_0^t i(t) dt = zFn = zFcV \quad [1]$$

where  $Q$  is the electrical charge in coulombs,  $i$  the current in amperes,  $t$  the time in seconds,  $z$  the number of electrons exchanged per analyte molecule,  $F$  the Faraday constant ( $96\,487\text{ C mol}^{-1}$ ),  $n$  the number of moles,  $c$  the molar concentration, and  $V$  the volume.

In coulometry, the analyte in the sample volume is exhausted completely. This distinguishes the method from amperometry or voltammetry where the level of current is measured, which is controlled by the concentration through its influence on the rate of

diffusion. This means that in coulometry, in contrast to most analytical methods, it is not the concentration that is determined but the total amount of analyte. From the knowledge of the volume it is, however, possible, of course, to derive the concentration. As electrical charge can be measured with high accuracy and precision, the method is an absolute method, i.e., calibration with standard solutions is not necessary. This is the aspect coulometry has in common with the classical methods of gravimetry and titrimetry and also with electrogravimetry. However, in contrast to electrogravimetry, the other electrochemical bulk method, the product of the redox reaction does not have to form a weighable solid deposit on an electrode. This makes coulometry a much more versatile option.

There are two options. Coulometry can be conducted in the constant current and the constant potential modes. The former is inherently simpler as in this case the total charge is obtained directly from the measured time to the completion of the reaction. However, it can only be used successfully if there is only one redox-active species present in the sample or if at least the redox potentials of species present are succinctly different. In constant current coulometry, the cell voltage needs to follow the depletion of the concentration of the analyte according to Nernst's law (for an oxidation):

$$E = E_F^\circ + \frac{RT}{nF} \ln \frac{x}{1-x} \quad [2]$$

where  $E$  is the electrode potential,  $E_F^\circ$  the standard formal potential for the species being oxidized,  $R$  the universal gas constant,  $T$  the absolute temperature in Kelvin, and  $n$  the number of electrons exchanged for each molecule;  $x$  is the fraction of analyte oxidized.

From an examination of eqn [2] it follows that, for example, for 99.9% completion of the reaction, the applied voltage has to be  $\sim 180\text{ mV}$  more positive than at the start (for  $n = 1$ ).

In order to continue to pass the current through the cell, eventually an alternate reaction has to set in, such as the decomposition of the solvent or the electrode material. This leads to the voltage behavior shown in Figure 1.

Constant potential coulometry allows better control as electrode reactions are always governed by the electrode potential. Interfering reactions can be avoided as long as their redox potentials are sufficiently distinct. It may also be possible to

**Figure 1** Potential change during constant current coulometry. The secondary reaction is due to oxidation or reduction of a further electroactive species in the sample or decomposition of the electrode or solvent.

quantitatively remove an interfering species before the determination of the analyte, a process termed electroseparation, or to sequentially determine several analytes. In constant potential coulometry the current,  $i_t$ , decays with time according to eqn [3]:

$$i_t = i_0 \cdot 10^{-kt} \quad [3]$$

$i_0$  is the initial current,  $t$  the time, and  $k$  a constant dependent on such parameters as the electrode size and the diffusion coefficient of the species analyzed (see Figure 2).

It is therefore necessary to integrate the area under the curve to obtain the charge. Today this is readily achieved by electronic or computational methods and is not a hindrance, and precisions of better than 0.1% can be achieved. Such levels of precision are scarcely attainable with other instrumental methods.

A possible side reaction to be avoided is the decomposition of the solvent, which in most cases is water. Therefore, it has to be made sure that the pH-dependent potential stability boundaries of water are not exceeded in order to assure 100% current efficiency for the analytical process. For reductions it is often beneficial, as it is in other electrochemical methods, to use mercury electrodes because the reduction of water, i.e., the evolution of hydrogen, is kinetically hindered on this material. Therefore, the reduction of species such as metals with redox potentials more negative than that of hydrogen is enabled. For anodic processes, i.e., oxidations, the

**Figure 2** Current decay on a logarithmic scale during constant potential coulometry.

dissolution of the electrode material is also a potential interfering reaction. Mercury is not suitable for such applications and glassy carbon should be used instead. For reductions, ambient oxygen dissolved in the sample solution will interfere by its reduction to hydrogen peroxide. Deoxygenation by passing a stream of nitrogen or other inert gas through the solution before analysis might therefore be necessary. Attention also has to be paid to potential secondary interfering reactions. It is, for example, possible to reduce  $\text{Cr}^{3+}$  to  $\text{Cr}^{2+}$ , but  $\text{Cr}^{2+}$  will react with protons in acidic solutions to yield again  $\text{Cr}^{3+}$  as product, thus lowering the Faradaic efficiency to below 100%. For very small analytical concentrations, non-Faradaic, capacitive charging currents at the working electrode will not be negligible and limit the lowest amount of charge measurable with adequate precision to  $\sim 10 \mu\text{C}$ . This corresponds to an ultimate mass detection limit of  $\sim 0.1 \text{ nmol}$  or  $\sim 1 \text{ ng}$  of analyte.

## Instrumentation

### Constant Current Coulometry

A constant current source can be approximated by simply using a voltage source of a relatively high level in series with a current control resistor. However, changes in cell voltage will cause an error in current in this arrangement (which is the smaller the higher the source voltage is) and therefore it is better to use a galvanostat. Stand-alone galvanostats are not widely available commercially these days, but some commercial potentiostats feature the galvanostatic mode as an option. Most commercial

**Figure 3** Standard galvanostat circuitry for constant current coulometry consisting of a voltage source, a resistor, and an operational amplifier.

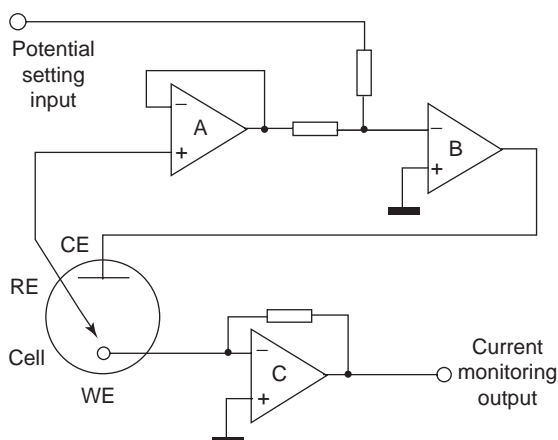

potentiostats (those using a standard internal electronic circuitry) without provision for galvanostatic experiments may be forced to work in the galvanostatic mode by inserting a resistor between the inputs for the working and reference electrodes and then connecting the working electrode to the reference input. A reference electrode is then not used. The current forced through the cell is determined by the potential set at the potentiostat and the resistor according to Ohm's law. It is also possible to construct a galvanostat that is perfectly adequate for the small currents used in analysis relatively easily and at low cost using a single operational amplifier as illustrated in Figure 3.

### Constant Potential Coulometry

Constant potential coulometry requires the presence of a reference electrode in solution, besides working and counter-electrodes, and the use of a potentiostat in order to accurately set the applied potential (see Figure 4).

## Methods

It is possible to distinguish between direct and indirect, or primary and secondary, coulometry, denoting methods in which either the analyte is oxidized or reduced directly at the working electrode, or in which a substance is generated at the working electrode which then reacts with the analyte. The latter procedure is also termed coulometric titration considering that the working electrode serves for the production of a titrant. Note that sometimes direct coulometry has also been termed a titration, a view in which electrons are seen as reagent. Coulometry may also be employed in a flow-through mode, which has found special applications.

**Figure 4** Basic potentiostat circuitry for constant potential coulometry. Amplifier A allows the current-free monitoring of the potential of the reference electrode RE, amplifier B regulates the potential at the working electrode WE, and amplifier C converts the current passing through the cell CE into a proportional voltage.

### Direct Coulometry

The analyte is directly oxidized or reduced at a working electrode and the charge required is determined. This may be carried out in either the constant current or the constant potential mode, but the latter is preferable because of the better control of side reactions. The completeness of the reaction is then indicated by the decay of the current toward zero. The reaction is stopped when the current has decayed to a predetermined fraction of its initial value such as 1 or 0.1%, assuming that this will give ~99 or 99.9% accuracy. However, it is often difficult to set a potential that assures complete reaction of the analyte whilst avoiding side reactions such as the decomposition of solvent. Stirring of the solution is required for enhancement of the transport of the analyte to the electrode but the current is still predominantly controlled by the diffusion through the stagnant non-stirred layer adhering to the electrode. For low concentrations the diffusion rate is low and therefore the current small (in the constant current mode this has to be set low). This means that the method tends to be slow. To overcome some of these difficulties, often a mediator is added that carries the current when the concentration of the analyte becomes low. This mediator then reacts in turn with the analyte so that the condition of 100% current efficiency is maintained. For example, iron may be determined by oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  at a working electrode. However, as the concentration of  $\text{Fe}^{2+}$  decreases, potentials at which water is oxidized are required to complete the iron determination. This side reaction can be avoided if  $\text{Ce}^{3+}$  is added to the solution.

$\text{Ce}^{3+}$  is readily oxidized to  $\text{Ce}^{4+}$  at modest anodic potential where water oxidation is not yet taking place and this reaction will set in once  $\text{Fe}^{2+}$  has been depleted to some extent. However,  $\text{Ce}^{4+}$  readily oxidizes available  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  so that the remaining iron is determined indirectly. This approach should not be confused with coulometric titrations described below.

### Coulometric Titrations

In indirect coulometry, an intermediate reagent, or titrant, is produced by the electrode reaction and the analyte never reacts directly at the working electrode. Titrations are more widely used than direct methods because they overcome the disadvantages of the latter. The starting material for electrochemical generation of the reagent can be provided at sufficient concentration to sustain a high current so that the determination can be carried out more rapidly. This also minimizes the chance of side reactions and the constant current mode can be adopted. One disadvantage compared to direct coulometry is that both reactions, the generating electrode reaction and the subsequent reaction with the analyte, need to be 100% efficient. On the other hand, the method is much more flexible as it is possible to generate titrants by electrode reactions not only for redox titrations but also for the other three types of titration. In coulometric titrations, a method of endpoint detection is needed, just as in conventional volumetric titrations. Preferentially an instrumental method is adopted. In comparison to conventional titrations the coulometric mode has several advantages as long as a suitable generating reaction is available. Complete automation is simpler. The expense of a precise mechanical automatic burette is avoided. The use of unstable reagents is possible as these are produced *in situ* and species not normally used for conventional titrations such as  $\text{Cl}_2$ ,  $\text{Br}_2$ ,  $\text{Ag}^{2+}$ , or  $\text{Cu}^+$  are feasible. Calibration of a reagent solution is not necessary. The sensitivity is also higher than for classical titrations as smaller amounts of reagent can be delivered with accuracy than dispensed volumetrically. This is illustrated by the fact that a current of  $10\text{ }\mu\text{A}$  flowing over a period of 10 s corresponds to only about  $10^{-9}$  mol of analyte. Measuring currents and times of that order accurately is readily achieved with modern instrumentation.

A cell for coulometric titration is illustrated in Figure 5.

The counter-electrode reaction often interferes and for this reason this electrode is usually physically separated from the sample solution by using a diaphragm or frit to create a liquid junction. External

**Figure 5** Cell arrangement for coulometric titration in the constant current mode. The counter-electrode is isolated from the sample solution by a liquid junction formed, for example, with a glass frit. The indicator electrodes may belong to a potentiometric, amperometric, or conductometric detection system.

generation is also possible by employing a flow-through arrangement that delivers the desired product from the electrode to the sample.

All of the four types of titrations have been implemented coulometrically (i.e., acid-base, precipitation, complexometric, and redox titrations). Acid-base titrations are achieved by generating protons or hydroxide ions from the solvent water by electrolysis (the hydrogen and oxygen evolution reactions). A list of possible methods is given in Table 1.

The means of detecting the endpoint will be dictated by the type of reaction employed. Acid-base titrations are most easily followed using a glass pH electrode while redox reactions lend themselves to amperometric detection (only a small fraction of the species detected is consumed at the indicator electrode). Other options are ion-selective electrodes and conductometric detection.

### Coulometric Detection in Flow Methods

Coulometry may be employed for detection in flow-injection analysis (FIA), an approach to automation of sample handling and processing, or in separation methods such as HPLC. Note that these methods are closely related to amperometric detection. The distinction is in the degree at which the analyte is converted. A high Faradaic efficiency is desirable in any case and 100% efficiency might actually be

**Table 1** Examples of coulometric titrations

**Figure 6** Wall jet electrode for flow through coulometry.

achieved in methods nominally termed amperometric.

The wall jet cell arrangement commonly used in flow-through detection is illustrated in **Figure 6**.

Complete analyte reaction is assured by designing the cell in such a way that the ratio of electrode area to cell volume is large, so that each analyte molecule can reach the electrode during its residence time in the cell.

Applications are mostly based on oxidations, as the complete removal of oxygen needed for reduction reactions is difficult to achieve in flow-through systems. However, the flow-through approach elegantly allows discrimination against residual currents, due to electrode charging or Faradaic reactions of impurities, by enabling the measurement of transient

**Figure 7** Current peak obtained in flow through methods. The charge is obtained by integration of the peak area on top of a baseline current between the limits indicated.

coulometric peaks on top of baseline currents (see **Figure 7**).

FIA with coulometric detection is suitable when only one or few electroactive species are present and potential control assures selectivity. A typical application for an FIA system with coulometric detection is the determination of SO<sub>2</sub> in wine.

For more complex samples with a number of electroactive species to be determined, separation by HPLC, or other methods such as ion chromatography or capillary electrophoresis, followed by coulometric detection is better suited. Its applications in HPLC are usually to oxidizable organic species that cannot be determined by ultraviolet absorption, the standard detection technique in HPLC. Examples for such species include amines and phenols, catecholamines (such as the neurotransmitters adrenaline and

dopamine), vitamin A, carbohydrates, ketones, and nitrocompounds. The sensitivity of coulometric detection in HPLC is high; detection limits down to  $\sim 10^{-8} \text{ mol l}^{-1}$  have been achieved. For certain applications it is necessary to adopt pulsing methods in which the electrode is continuously cleaned electrochemically by applying an oxidizing voltage followed by a reducing voltage before applying an intermediate working potential. This is necessary if the oxidation products of the analyte lead to poisoning of the electrode. Indirect coulometric detection for HPLC, in which a reactive intermediate is formed at the working electrode, similarly to coulometric titration, has also been reported. Postcolumn reaction of analytes that are not natively electroactive before detection may also be adopted, for example, for the determination of amino acids.

Flow-through methods are also used for sample treatment prior to coulometric titration, for the purpose of cleanup or preconcentration on an ion-exchange column or for reduction to a desired oxidation state in reductor columns. Preadjustment of redox states or removal of interferents may also be carried out by an auxiliary electrochemical flow-through cell located ahead of the analytical cell.

### Stripping Coulometry

Sensitive determination of metal ions is possible via coulometry by using preconcentration. Thereby the metals are first deposited by reduction onto a mercury drop or film or a porous carbon electrode. In a second step the metals are stripped by oxidation and the resulting charge is measured in the form of a peak allowing discrimination against background currents. Deoxygenation of the sample is generally not necessary in this procedure. Calibration-free determinations of heavy metals following this procedure at concentrations as low as 1 ppb have been reported.

### Determination of Water by the Karl Fischer Titration

A very common application of coulometry is in the determination of water by the Karl Fischer method.

Water reacts with iodine and sulfur dioxide according to the following reaction:

In order to achieve complete reaction, pyridine is added to bind the protons produced in the reaction. Pyridine also increases the solubility of iodine and sulfur dioxide by complex formation. The reagents are dissolved, and the reaction is carried out, in methanol or ethylene glycol monomethyl ether as

solvent to allow polar substances from the sample to be dissolved. Because of the toxicity of pyridine, this reagent is now often replaced with other bases, such as diethanolamine or imidazole, or salts of weak organic acids such as sodium salicylate.

The Karl Fischer titration may be carried out volumetrically by using a mixture of the three compounds in a mole ratio of 1:3:10 (iodine, sulfur dioxide, pyridine), in which sulfur dioxide is present in excess. The reagent mixture is commercially available or readily made. In the coulometric Karl Fischer method, which has the usual advantages of coulometric titrations of easier automation and reagent handling as well as higher sensitivity, iodine is generated anodically from iodide in the reagent solution by the application of a fixed current of typically  $10 \mu\text{A}$  to two inert platinum electrodes in solution. Before the endpoint is reached, the current is maintained by oxidation of iodide produced in the titration reaction on the anode and the reduction of  $\text{H}^+$  on the cathode. The required voltage between the electrodes is  $\sim 300 \text{ mV}$  and corresponds roughly to the difference in standard potentials for the two redox reactions. After the endpoint, excess iodine is present in solution and the reduction of this species can carry the cathode current. As the iodine/iodide redox couple is well reversible, the cell voltage drops rapidly to a few millivolts only giving a very sharp indication of the endpoint. This mode of endpoint detection is also used in volumetric Karl Fischer titration. It is then usually termed biamperometric detection, although it still involves a constant current approach, because it is based on two electrode reactions of interest. It is then the oxidation of iodide produced in the titration reaction that carries the current (see Figure 8).

Karl Fischer titrations are frequently used for the analysis of water content in such samples as food materials, pharmaceuticals, and solvents used in industrial applications, or for the determination of hydration water in crystals. Dedicated units are commercially available and many automatic titrators or pH meters feature a connector for current biased voltage measurements labeled 'Karl-Fischer' or simply 'KF'.

### Layer Thickness

The layer of an easily oxidizable surface layer of metal may be dissolved anodically under potential control. If the area of the sample surface is known the layer thickness can be deduced from the total charge needed for complete stripping. A typical application of this procedure is the analysis of a layer of anticorrosive tin on steel.

**Figure 8** Voltage drop obtained in coulometric Karl Fischer titrations indicating the endpoint.

### Determination of Gaseous Species

Coulometry in different variants is also used for the determination of gaseous species. Carbon dioxide or sulfur dioxide dissolved in beverages may be determined by sweeping these dissolved gases with nitrogen from a sample into an absorbing solution followed by coulometric titration in a batch or flow-through system. Samples may also be combusted with oxygen in a closed system and the resultant gases titrated. This approach is mainly used for the determination of total carbon content. Another application is the determination of the amount of chlorinated hydrocarbons present in a sample by determining hydrochloric acid liberated in the combustion.

### Coulometric Microtitrators

A relatively recent development has been the construction of microscale coulometric acid–base titrators using microlithographic techniques. One or more inert working electrodes (typically made from gold) are placed at a distance of typically 50  $\mu\text{m}$  from a solid-state pH sensor typically in the form of an ion-sensitive field effect transistor (ISFET). The working electrode, the actuator, is used to either generate protons or hydroxide ions by electrolysis of water at constant current. The thus created reagent diffuses away from the generator electrode in all directions but is consumed by the analyte. Therefore, a pH gradient moving outward results. This is defined by the rate of reagent generation but delayed by the buffering action of the analyte in dependence of its concentration. The pH-ISFET serves to sense this

**Figure 9** Possible arrangement of electrodes for a channel-based coulometric microtitrator. Two actuator electrodes at which protons or hydroxide ions are produced by electrolysis of water encompass a sensing solid-state pH electrode. The reference electrode belongs to the potentiometric pH electrode while the counter-electrode carries the actuator current and is removed from the working electrode to prevent interference.

gradient and the signal indicates the endpoint. The counter-electrode, where the complementary, but interfering, water electrolysis reaction is taking place is sufficiently far removed from the working electrode so that the titration is completed before the cloud of acid or base reaches the detection zone. The small dimensions of the entire assembly allow the placement of all electrodes at the tip of a probe the size of a conventional pH electrode. As the diffusion across the spacing between the working electrode and the pH sensor is very fast, the entire titration is completed in a few seconds. In contrast to conventional coulometric titration only a negligibly small fraction of the analyte is consumed. The analysis may be carried out repeatedly in the same sample. The sample is not stirred during the titration in order not to perturb the diffusion process. It is, however, necessary to carry out a calibration of the system. Coulometry carried out in this fashion is not an absolute method as diffusion is introduced as a variable parameter (see Figure 9).

## Introduction

Countercurrent chromatography (CCC) is a type of liquid partition chromatography and has the distinct advantage of operation without the use of a solid support. Since no solid support is used, complications arising from the use of a solid support, such as adsorptive sample loss and denaturation, tailing of solute peaks, and contamination, can be avoided in CCC. Different from most types of liquid chromatography, CCC utilizes two immiscible solvent phases and the partition process takes place in an open column space where one phase (stationary phase) is retained and the other phase (mobile phase) continuously passes through it. In order to retain the optimum amount of the stationary phase in the column, the system uses appropriate combinations of various column configurations and the applied force field (gravitational or centrifugal). Hence, the CCC instruments display a variety of forms that are quite different from those used in conventional liquid chromatography.

All the existing CCC systems may be divided into two classes: hydrostatic equilibrium systems and hydrodynamic equilibrium systems. The hydrostatic system uses a stable force field to retain the stationary phase in the column while the mobile phase is flowing through the column. The CCC systems that belong to this category are helix CCC (toroidal coil CCC), droplet CCC, locular CCC, and centrifugal partition chromatography (CPC). On the other hand, the hydrodynamic system employs an Archimedean screw effect that facilitates constant mixing of the two phases while retaining one of the phases as a stationary phase. It includes high-speed CCC, nonsynchronous CCC, and slow rotary CCC.

## Hydrostatic CCC Systems

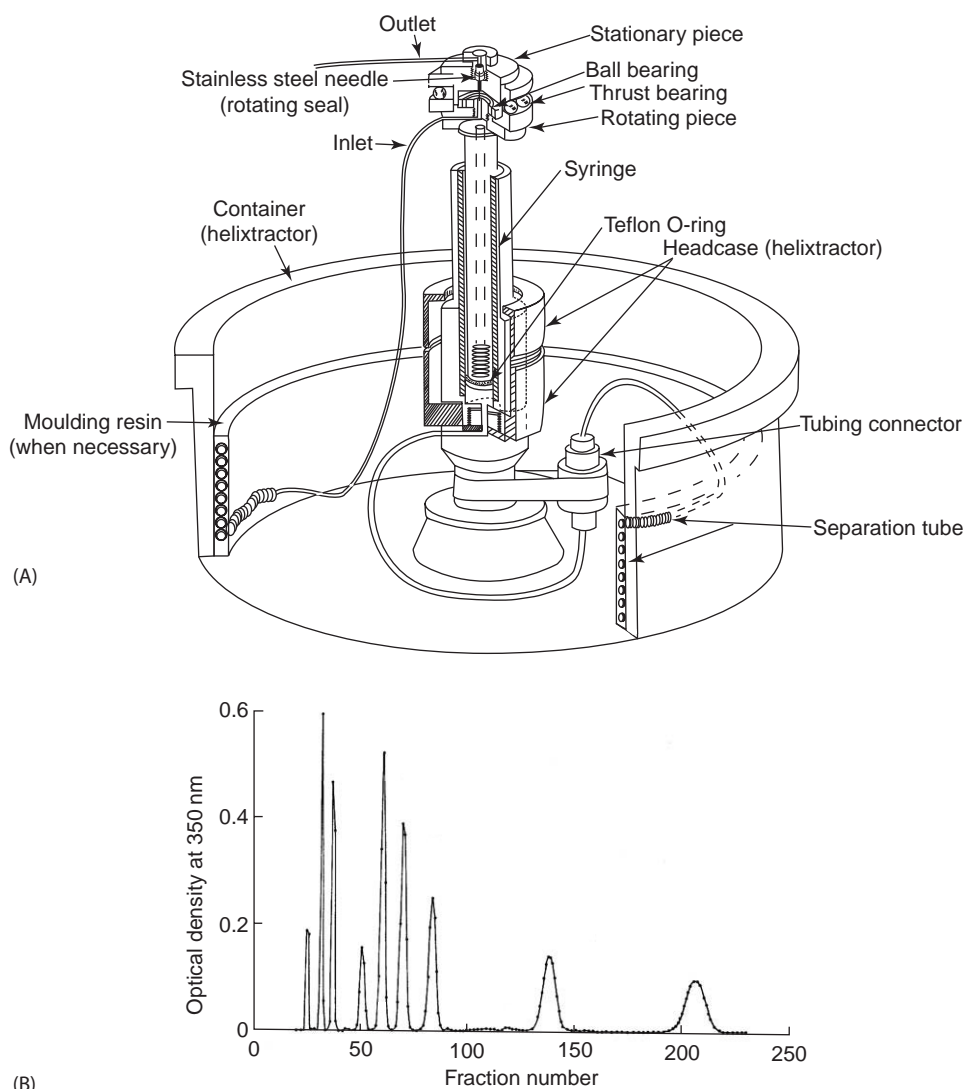

### Helix CCC (Toroidal Coil CCC)

This is the original CCC system that was given the name ‘countercurrent chromatography’ in 1970. It uses a long, fine coiled tube on a flexible core (6 mm OD) that is again coiled around the periphery of a centrifuge bowl (toroidal coil). Rotation of the bowl creates a strong centrifugal force field that retains the stationary phase, either lighter or heavier phase in each helical turn. The mobile phase is introduced into the inlet of the coiled column while the effluent is continuously monitored and collected into test tubes as in liquid chromatography. The original model (Figure 1A) was equipped with a rotating syringe to feed the mobile phase while the effluent from the outlet of the column was collected through a rotary seal. Later, this design was replaced by a seal-free flow-through system to eliminate the risk of leakage of the solvent and cross-contamination at the rotary seal. The system yields a high partition efficiency of several thousand theoretical plates as demonstrated by the separation of DNP (dinitrophenyl)-amino acid (Figure 1B). The partition efficiency of the column increases with the number of helical turns and/or when the core is made smaller and the inner diameters of the coiled tube are reduced. The limitation is the hydrostatic pressure accumulated in the column, which eventually breaks the tubing. This hydrostatic pressure ( $P$ ) is expressed by the following formula:

$$P = R\omega^2(\rho_1 - \rho_2)nd \quad [1]$$

where  $R$  denotes the distance between the center of rotation and the axis of the helix,  $\omega$  the angular velocity of rotation,  $n$  the number of coil units,  $d$  the distance between a pair of interfaces in each turn (less than the core OD), and  $\rho_1$  and  $\rho_2$ , the densities of heavier and lighter phases, respectively.

This analytical CCC method also requires careful optimization of the flow rate, which maximizes the partition efficiency and the retention of the stationary phase. A higher flow rate will result in higher column pressure and lower partition efficiency with the loss of the stationary phase from the column, whereas a lower flow rate requires a longer elution time.

**Figure 1** Design and performance of the helix CCC apparatus: (A) Original design of the centrifuge head of helix CCC; and (B) DNP (dinitrophenyl) amino acid separation by helix CCC. Peaks identified in order of elution and their partition coefficient ( $C_{\text{upper phase}}/C_{\text{lower phase}}$ ) from left to right are: *N*-DNP- $\delta$ -L-ornithine (>100); *N*-DNP-L-aspartic acid (3.8); *N*-DNP-D,L-glutamic acid (1.9); *N,N*-di-DNP-L-cystine (0.94); *N*-DNP- $\beta$ -alanine (0.71); *N*-DNP-L-alanine (0.56); *N*-DNP-L-proline (0.45); *N*-DNP-L-valine (0.26); and *N*-DNP-L-leucine (0.18). Solvent system: chloroform/acetic acid/0.1 mol l<sup>-1</sup> HCl (2:2:1), upper aqueous phase mobile at 125  $\mu$ l h<sup>-1</sup>. The total elution time: ~40 h.

### Droplet CCC

This simple preparative CCC system grew out of the observation that the light phase with a low wall affinity formed discrete droplets that rose through the heavy phase with a visible evidence of very active interfacial motion. Under ideal conditions, each droplet could become a plate if kept more or less discrete throughout the system. The actual system was made of long vertical columns of narrow bore silanized-glass tubing with fine Teflon tubes to interconnect the wider bore glass tubes. Discrete droplets, formed at the tips of the finer tube inserted into the bottom of the long glass tube, were made to

follow one another with minimal space between them and at a diameter close to that of the internal bore of the column (Figure 2). These droplets divide the column into discrete segments that prevent longitudinal sample band spreading along the length of the column as they mix locally near the equilibrium. The fine Teflon tubing interconnecting the individual columns preserves the integrity of the partitioning with minimum longitudinal diffusion and helps in the formation of new droplets at the bottom of the next column. This regularity of droplet size and close spacing, a droplet size nearly filling the bore, and thin return tubing are important for best results.

**Figure 2** Droplet CCC system. Droplets formed at each column junction can travel through the column a rate of  $\sim 2 \text{ cm s}^{-1}$  without coalescence.

**Figure 3** Mechanism of rotation locular CCC apparatus.

The first prototype column assembly consisted of 300 glass tubes (60 cm long and 1.8 mm ID) and had a total capacity of 540 ml including  $\sim 16\%$  dead space in connections. Using a two-phase solvent system composed of chloroform, acetic acid, and 0.1 N HCl (2:2:1), several hundred milligrams of DNP-amino acids were separated within 80 h with an efficiency of 900 theoretical plates (TPs).

### Locular CCC

This CCC system was developed to compensate for the limitations of droplet CCC, which requires adequate droplet formation. **Figure 3** illustrates the column design and mechanism of rotation locular CCC. The column is made by inserting centrally perforated disks into the tubular column at regular intervals to form multiple compartments called 'locules'. Both retention of the stationary phase and interfacial area in each locule are optimized by inclination of the column while the mixing of the two phases is introduced by the rotation of the column.

**Figure 4** Schematic view of the centrifugal partition chromatograph.

The system permits universal application of the conventional two-phase solvent systems with either upper or lower phase as the mobile phase. Necessity of rotary seals at each terminal may be eliminated by gyration locular CCC in which the locular column is held vertical and gyrated to introduce circular motion of the two phases and their interface within each locule.

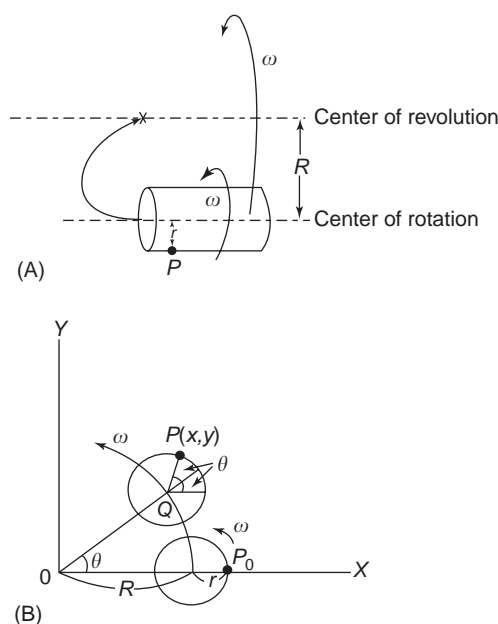

### Centrifugal Partition Chromatography

This CCC system is considered to be a hybrid of helix CCC and locular CCC. The doughnut-shaped separation column consists of a set of disks, each containing a number of small partition compartments interconnected with fine transfer ducts (**Figure 4**). Several units of these disks are stacked to form a column assembly. The whole column assembly is rotated with a flow-through centrifuge system equipped with a pair of rotary seals that can tolerate pressure up to  $60 \text{ kg cm}^{-2}$  ( $\sim 800 \text{ psi}$ ), and the whole system is computerized, as in liquid chromatography.

### Hydrodynamic CCC Systems

All hydrodynamic CCC systems utilize an Archimedean screw force that is created by coil rotation in the force field: some use low-speed rotation of the coil in unit gravity while others subject the coil to a high-speed planetary motion. An Archimedean force drives all objects in the coil toward one end of the coil, which is called the head; the other end is called the tail.

Since the low-speed rotary system is elsewhere in the encyclopedia, planetary centrifuge systems are reviewed here. All the centrifuge systems described

**Figure 5** Type-J synchronous planetary motion and resulting force field: (A) planetary motion; (B) coordinate system for computation of the acceleration field; and (C) centrifugal force distribution.

below use the seal-free flow-through mechanism to minimize the risk of leakage and cross-contamination.

### Type-J Multilayer Coil Planet Centrifuge

Figure 5 illustrates the type-J synchronous planetary motion of the coil holder and the resulting centrifugal force field. When the tubing is coaxially wound around the holder, the centrifugal force quickly separates the two-phase solvent system along the coil in such a way that one phase occupies the head side and the other the tail side.

This hydrodynamic behavior of the two phases can be effectively utilized for performing CCC as

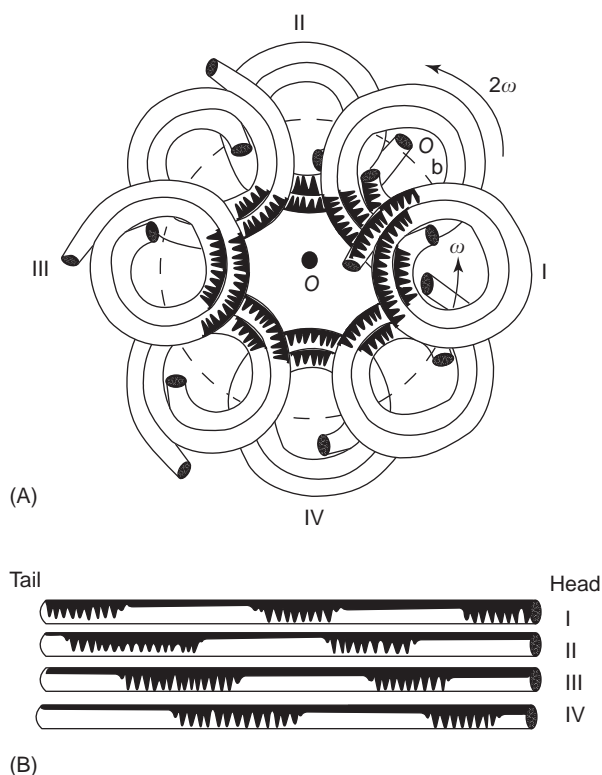

**Figure 6** Mechanism of high-speed CCC: (A) bilateral hydrodynamic distribution of the two phases in the coil, where the white phase occupies the head side and the black phase the tail side; (B) CCC operation utilizing the above hydrodynamic equilibrium condition; and (C) mechanism of dual CCC, where the two phases literally undergo countercurrent movement.

illustrated in Figure 6, where each coil is drawn as a straight tube. The coil at the top shows the bilateral hydrodynamic equilibrium where the white phase (head phase) occupies the head side and the black phase (tail phase) the tail side of the coil (Figure 6A). This equilibrium condition indicates that the white phase, if introduced at the tail, would move toward the head, and similarly the black phase introduced at the head would move toward the head. In Figure 6B, the upper coil is filled with the white phase and the black phase is introduced from the head end. The mobile phase (black) then travels rapidly through the coil, leaving a large volume of the stationary phase in the coil. Similarly, the lower coil is filled with the black phase and the white phase is introduced from the tail end. The mobile phase then travels through the coil, leaving a large volume of the stationary phase in the coil. In either case, solutes locally injected at the inlet of the coil are efficiently partitioned between the two phases and quickly eluted from the coil in the order of their partition coefficients, thus yielding high partition efficiency in a short separation time. The present system also permits simultaneous introduction of the two phases through the respective terminals, as illustrated in Figure 6C. This dual CCC operation requires an additional flow tube at each terminal to collect the effluent, and if desired a sample injection port is introduced at the middle portion of the coil. This system has been effectively applied to liquid-liquid dual CCC and foam CCC as described later.

The hydrodynamic distribution of the two solvent phases in the type-J planetary centrifuge has been

**Figure 7** Distribution of two immiscible solvent phases in the spiral column undergoing type-J synchronous planetary motion based on stroboscopic observation: (A) distribution of mixing and settling zones in the rotating spiral column and (B) motion of the mixing zones through the stretched spiral column.

observed under stroboscopic illumination. A spiral column was filled with the stationary phase and the colored mobile phase was eluted through the column in a proper elution mode. In the steady-state hydrodynamic equilibrium, the spiral column showed two distinct zones. As schematically illustrated in **Figure 7A**, vigorous mixing of the two solvent phases was observed in about one-fourth of the column area near the center of the centrifuge (mixing zone) while two phases are clearly separated into two layers in the rest of the area (settling zone). Because the location of the mixing zone is fixed to the centrifuge system, while the spiral column rotates about its own axis, each mixing zone is traveling through the spiral column at a rate of one round per revolution as shown in **Figure 7B**. This indicates an important fact that at any given portion of the column the two solvent phases are subjected to a repetitive partition cycle of mixing and settling at a high frequency of over 13 times per second at 800 rpm of column rotation. Because of its higher partition efficiency and speedy separation, the system was named 'high-speed CCC (HSCCC)'.

**Figure 8** shows the most advanced HSCCC centrifuge equipped with a set of three multilayer coils

**Figure 8** Photograph of HSCCC centrifuge equipped with a set of three multilayer coils connected in series.

**Figure 9** Separation of DNP-amino acid by HSCCC. Experimental conditions: Apparatus: type-J HSCCC centrifuge with a set of three multilayer coil separation columns; column: semianalytical, 1.07 mm ID and 270 ml capacity; sample: DNP-amino acid, 10 mg; solvent system: chloroform/acetic acid/0.1 N HCl (2:2:1); mobile phase: upper aqueous phase; flow rate: 3 ml min<sup>-1</sup>; revolution: 1250 rpm; retention of stationary phase: 41.5% of the total column capacity.

connected in series on the rotary frame. It can produce highly efficient separations in a few hours. A typical separation obtained by HSCCC is illustrated in **Figure 9**, where four DNP-amino acids are resolved at a high efficiency ranging from 4200 (DNP-L-aspartic acid) to 3000 (DNP-L-alanine) TPs in a few hours. As in high-performance liquid chromatography (HPLC), HSCCC can also be interfaced with a mass spectrometer.

Although the type-J HSCCC has been successfully used for wide variety of natural and synthetic products, it fails to retain polymer phase systems that are useful for the separation and purification of various proteins. In order to improve the retention of the stationary phase for these extremely viscous solvent systems, a cross-axis coil planet centrifuge has been introduced as described below.

**Figure 10** Planetary motion of holder in cross-axis CPC.

### Cross-Axis Coil Planet Centrifuge (Type-XL CPC)

This CCC system, which also belongs to a family of HSCCC, produces a characteristic planetary motion where the axis of the holder is perpendicular to the axis of the centrifuge (**Figure 10**). This modified planetary motion produces a complex pattern of the centrifugal force field fluctuating in a three-dimensional space, where one force vector acts across the diameter of the tube to enhance the separation of the two phases to improve the retention of the stationary phase. The ratio  $L/X$  (**Figure 10**) determines the retention stabilizing power, where  $L$  is the distance from the coil to the middle point of the rotary shaft, and  $X$  is the distance between the axis of the coil holder and the centrifuge axis. An apparatus such as the X-1.5L CPC has been successfully used for the separation of various recombinant enzymes with polymer phase systems as well as for large-scale preparative separation with polar solvent systems. Some examples are shown in **Figure 11** where recombinant uridine phosphorylase was purified by the X-1.5L CPC using a polymer phase system.

### Nonsynchronous Flow-Through Coil Planet Centrifuge

This most versatile coil planet centrifuge provides a freely adjustable coil rotation under a strong centrifugal force field produced by high-speed revolution, and yet the system does not require the use of a rotary seal. The apparatus is not yet commercially available probably due to its highly complex mechanical design (**Figure 12**).

This CCC system is ideal for the separation of biopolymers and bioparticles, such as proteins, nucleic

**Figure 11** Purification of recombinant uridine phosphorylase (Urd Pase) using polymer phase systems composed of 384 g of PEG (polyethylene glycol) 1000, 150 g each of  $\text{KH}_2\text{PO}_4$  and  $\text{K}_2\text{HPO}_4$  in 1716 g of water.

acids, mammalian cells and bacteria using polymer phase systems.

## Specific CCC Techniques

Recently two useful CCC techniques have been developed: pH-zone-refining CCC, which separates a large quantity of charged samples, and chiral CCC, which uses a ligand called chiral selector to separate enantiomers according to their affinity to the chiral selector.

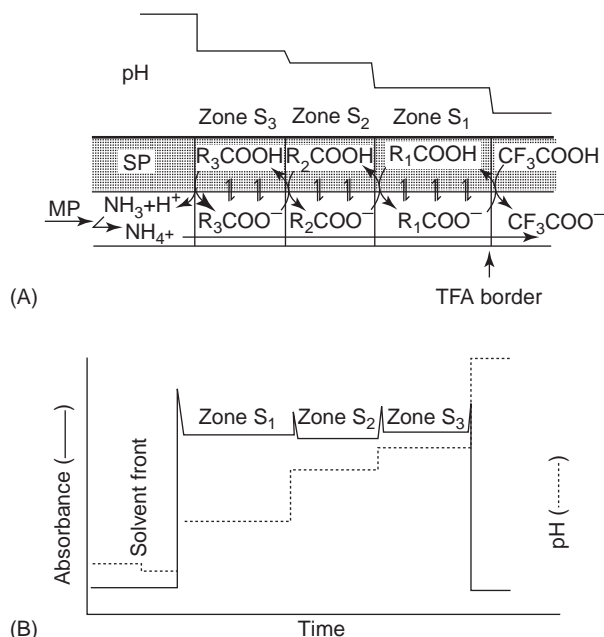

### pH-Zone-Refining CCC

This large-scale preparative CCC technique separates ionic compounds to produce a train of highly concentrated rectangular peaks fused together with minimum overlap, which is quite similar to that in displacement chromatography. The method uses a retainer in the stationary phase to retain the target compounds and an eluter in the mobile phase to elute them according to their hydrophobicity and  $\text{pK}_a$ . The most commonly used retainers are trifluoroacetic acid (TFA) for acidic samples and triethylamine for basic samples, while the eluter is usually ammonia for acidic samples and hydrochloric acid for basic samples.

Mechanism of pH-zone-refining CCC is shown in **Figure 13A**, which schematically illustrates a cross-sectional view of the separation column where three acidic compounds are eluted with a mobile phase containing ammonia and through a stationary phase containing TFA. Due to its nonlinear isotherm, the retainer (TFA) forms a sharp rear border that moves at a rate considerably lower than that of the mobile phase. Three analytes,  $S_1$ ,  $S_2$ , and  $S_3$ , competitively form solute zones behind the sharp TFA border according to their  $\text{pK}_a$  and hydrophobicity. Among

**Figure 12** Design of nonsynchronous flow-through CPC without rotary seals. Cross-sectional view through the central axis of the apparatus.

**Figure 13** Mechanism of pH-zone-refining CCC: (A) partition process within the column and (B) elution profile.

these,  $S_1$  with the lowest  $pK_a$  and hydrophobicity is located immediately behind the TFA border, while  $S_3$  with the highest  $pK_a$  and hydrophobicity is located at

the end of the solute zones where it forms a sharp trailing border. As indicated by curved arrows, proton transfer takes place at each zone boundary governed by the difference in pH between the neighboring zones. The loss of the solute from the mobile phase to the stationary phase at the zone front is compensated by its return at the back of each zone, while ammonium ion in the aqueous phase serves as counterion for all species. After equilibrium is reached three solute zones move at the same rate as that of the TFA border, while constantly maintaining their width and pH. Charged minor components present in each zone are efficiently eliminated either forward or backward according to their  $pK_a$  and hydrophobicity and eventually accumulate at the zone boundaries. Consequently, the three analytes elute as a train of rectangular peaks with sharp impurity peaks at their narrow boundaries, as illustrated in **Figure 13B**.

The zone pH ( $pH_{zone}$ ), which governs the order of the elution for a set of analytes, is expressed according to the following formula:

$$pH_{zone} = pK_a + \log \left\{ \left( \frac{K_D}{K_S} \right) - 1 \right\} \quad [2]$$

where  $K_D$  is the partition ratio of solute  $S$  ( $RCOOH$ ) and  $K_S$ , the partition constant.

**Figure 14** Separations of C&D Orange No.5 by pH-zone-refining CCC. Sample size: 350 mg (A); 1 g (B); and 5 g (C). Apparatus: HSCCC centrifuge with 10 cm revolution radius; column: semipreparative multilayer coil, mm  $\times$  1.6 mm ID, 325 ml capacity; solvent system: diethyl ether/acetonitrile/0.01 mol l<sup>-1</sup> aqueous ammonium acetate (pH 9 by ammonia) (4:1:5); Mobile phase: lower aqueous phase; retainer: TFA in the sample solution; flow rate: 3 ml min<sup>-1</sup>; revolution: 800 rpm; SF: solvent front.

Figure 14 illustrates the separation of D&C Orange No.5 by pH-zone-refining CCC where three chromatograms were obtained at different sample sizes of 350 mg, 1 g, and 5 g as indicated in the diagram. In each chromatogram, the shaded area represents fractions containing pure components. As clearly shown in this figure, increasing the sample size results in a proportional increase of the peak width, while the width of the mixing zone containing impurities remains the same. These results indicate one of the important advantages of the present technique, i.e., increasing the sample size gives a higher yield of pure fractions. A few other typical applications of pH-zone-refining CCC are illustrated in Figures 15A–15C, and its advantages over the standard CCC technique are summarized in Table 1.

### Chiral CCC

Analogous to liquid chromatography, CCC can be used for chiral separation by dissolving the chiral selector in the liquid stationary phase. The method has some advantages over liquid chromatography in that the amount of the chiral selector in the column can be much greater (since it is dissolved in the stationary phase) and the same column may be used for various kinds of chiral separations simply by changing the chiral selector in the stationary phase.

Figure 16 shows the separation of ( $\pm$ )DNB(di-nitrobenzoyl)-amino acids using a chiral selector,

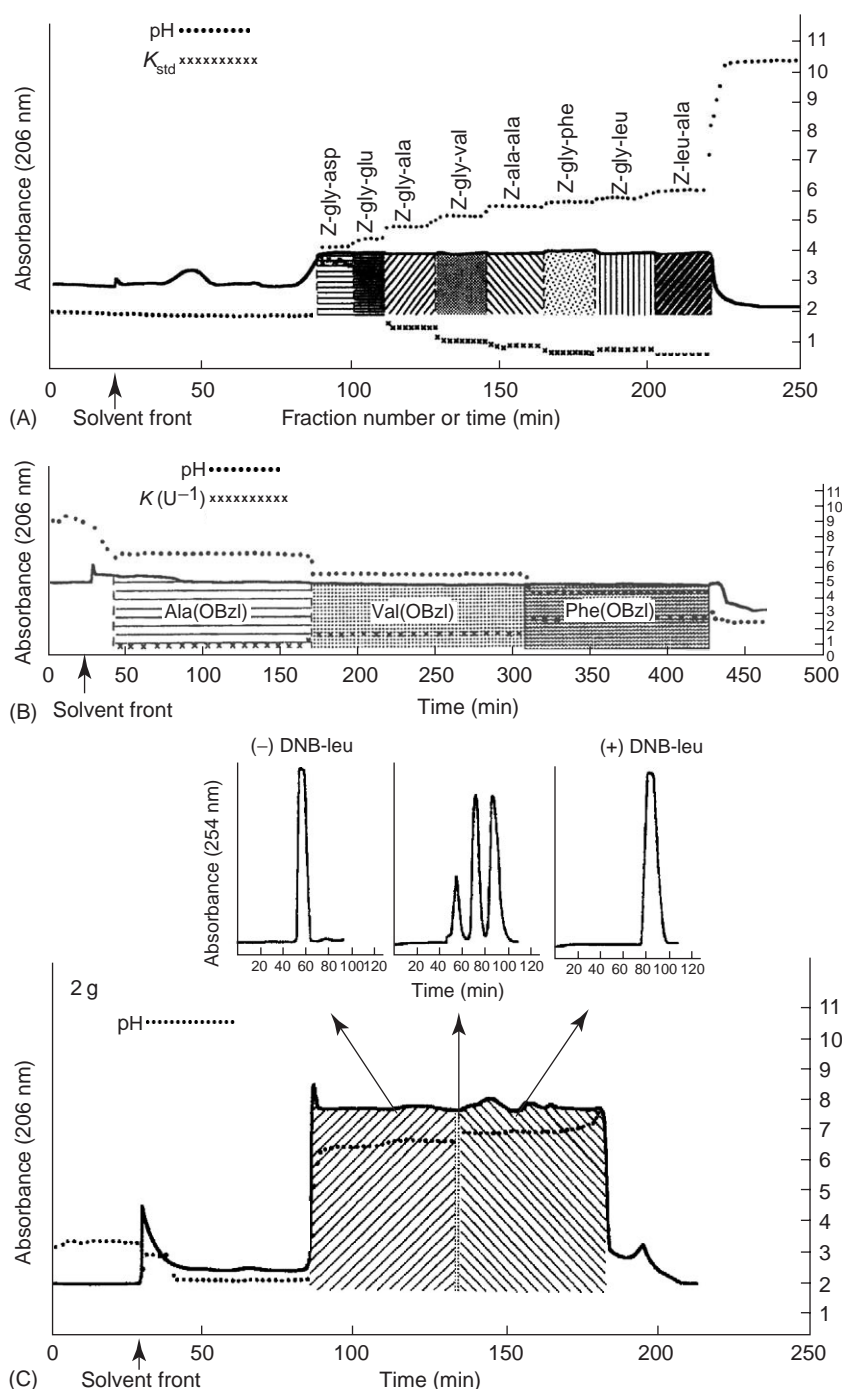

*N*-dodecanoyl-L-proline-3,5-dimethylanilide by HSCCC. The retention time of each enantiomer and its peak resolution are dependent on the  $K_F$  (formation constant) of chiral selector–amino acid complexes. Several ( $\pm$ )DNB-amino acids were resolved in a single run by adding the above chiral selector in the stationary phase.

A series of experiments on separation of ( $\pm$ )DNB-amino acids using the above chiral selector revealed that the peak resolution of the racemates are increased by (1) increasing the net amount or concentration of the chiral selector in the organic stationary phase and (2) adjusting the hydrophobicity of the solvent system so that the mean partition coefficient values for racemates fall between 0.6 and 0.8. The peak resolution will be further increased by the use of a longer and/or greater ID coiled column.

One of the advantages of chiral CCC over the conventional chiral chromatographic technique is that the method can be used to determine  $K_F$  (formation constant) of the chiral selector and target enantiomer.

### Dual CCC

As mentioned earlier, the type-J CPC can be used for dual CCC where two solvent phases literally countercurrent through a coiled tube (Figure 6C). In this system both polar and nonpolar components are eluted from the column in the respective outlet while the components with their partition coefficients at

**Figure 15** Examples of chromatograms obtained by pH-zone-refining CCC: (A) Separation of Z or CBZ(*N*-carbobenzoxy)-peptides. Solvent system: methyl-*tert*-butyl ether/acetonitrile/water (2:2:3), 16 mmol l<sup>-1</sup> TFA in organic stationary phase (pH 1.83) and 5.5 mmol l<sup>-1</sup> NH<sub>3</sub> in aqueous mobile phase (pH 10.62); sample: eight CBZ(*Z*)-dipeptides as indicated, each 100 mg dissolved in 50 ml solvent (25 ml each phase); flow rate: 3.3 ml min<sup>-1</sup>, head-to-tail elution mode; revolution: 800 rpm; (B) Separation of amino acid benzylesters. Solvent system: methyl-*tert*-butyl ether/water, 5 mmol l<sup>-1</sup> triethylamine in organic stationary phase and 20 mmol l<sup>-1</sup> HCl in aqueous mobile phase; sample: ala(OBzl), val(OBzl), and phe(OBzl) each 3.3 g in 100 ml of solvent; flow rate: 3 ml min<sup>-1</sup>; revolution: 800 rpm; and (C) Separation of (±)DNB(dinitro-benzoyl)-leucine using chiral selector. Solvent system: methyl-*tert*-butyl ether/water, TFA (40 mmol l<sup>-1</sup>) + chiral selector DPA (*N*-dodecanoyl-L-proline-3,5-dimethylanilide) (40 mmol l<sup>-1</sup>) in organic stationary phase and ammonia (20 mmol l<sup>-1</sup>) in aqueous mobile phase; sample: (±)-DNB-leucine 2 g; flow rate: 3 ml min<sup>-1</sup>; elution mode: head to tail; revolution: 800 rpm. (Analytical HSCCC was carried out using the same column by the standard CCC technique under the following conditions: solvent system: hexane/ethyl acetate/methanol/10 mmol l<sup>-1</sup> HCl (8:2:5:5), organic stationary phase containing DPA (20 mmol l<sup>-1</sup>); flow rate: 3 ml min<sup>-1</sup>; elution mode: head to tail; revolution: 800 rpm. All separations (A–C) were performed with the apparatus and column described in the **Figure 14** caption.)

near unity are retained in the column for a long period of time. The method is ideal for sample cleaning up for mass spectrometric analysis, since the repetitive sample injection is possible without loss of the stationary phase and minimum accumulation of impurities in the column.

The system also provides unique application to foam separation in which gas and liquid phases undergo a true countercurrent movement through a

long narrow coiled tube. When the liquid phase contains a surfactant, the dual countercurrent process produces a foaming stream that moves toward the tail. The sample mixture introduced at the middle portion of the column is separated according to their foam affinity: foam-active components are quickly carried with the foaming stream toward the tail whereas the remainder is carried in the liquid stream in the opposite direction and collected at the head end of the coil. Also for samples with a strong foaming capacity such as proteins and peptides (bactracin), foam CCC can be performed without surfactant in the liquid phase.

**Table 1** Advantages of pH-zone-refining CCC over standard HSCCC

Sample size	Applicable sample size is increased over 10 times for a given column
Fraction	Eluted fractions are highly concentrated to near saturation
Yield	Higher the sample size, the greater the yield of pure fractions
Minor components	Charged minor components are concentrated and accumulated at zone boundaries
Detection	Solute with nonchromophore can be monitored with pH

## Selection of Two-Phase Solvent Systems

The procedure of CCC is somewhat similar to that for liquid chromatography except that CCC uses two solvent phases that should provide a suitable partition coefficient ( $K$ ) to the target compounds as well as satisfactory retention of the stationary phase in the column.

**Figure 16** Chiral separation by HS-CCC. One step separation of various ( $\pm$ ) DNB amino acids by HS-CCC with the chiral selector DPA (*N*-dodecanoyl-L-proline-3,5-dimethylanilide) in the stationary phase (lower chromatogram). Upper chromatogram was obtained without the chiral selector in the stationary phase under otherwise identical experimental conditions. Solvent system: Apparatus and column: analytical HS-CCC centrifuge with a set of three multilayer coils (0.85 mm ID Teflon tubing) connected in series with a total capacity of 60 ml; solvent system: hexane/ethyl acetate/methanol/10 mmol l<sup>-1</sup> HCl (8:2:5:5) without ligand (upper chromatogram) and with a ligand DPA 1.6 g in the stationary phase (lower chromatogram); flow rate: 1 ml min<sup>-1</sup>; elution mode: head to tail; sample: 10 mg each of ( $\pm$ ) DNB amino acids indicated in the chromatogram dissolved in 2 ml of solvent (1 ml each phase); revolution: 1000 rpm.

### Partition Coefficient ( $K$ )

Since CCC uses two-solvent phases, the solute partition coefficient can be easily determined by a test tube experiment prior to the separation. In each measurement the sample is first partitioned between the two equilibrated solvent phases in a test tube, an aliquot of each phase is diluted with a suitable solvent, and then the concentration of the solute in each solution is determined by a spectrophotometer. Also, other methods such as radioactivity, enzymatic activity can be used. The partition coefficient,  $K$ , is the ratio between these two measurements and is usually expressed as solute concentration in the stationary phase divided by that of the mobile phase. When the sample is a mixture of multiple components, the partition coefficient of each component can be obtained by HPLC, gas chromatography, or thin-layer chromatography of each phase in the test tube and by comparing the peak height or area between the corresponding peaks in the two chromatograms. In general, the most suitable range of  $K$  values is  $1 \leq K \leq 2$  for hydrostatic CCC systems and  $0.5 \leq K \leq 1$  for hydrodynamic CCC systems. Once the  $K$  value is determined, the retention volume of the solute can be computed from the following equation:

$$V_R = V_{SF} + K(V_C - V_{SF}) \quad [3]$$

where  $V_R$  is the retention volume of the solute,  $V_{SF}$  the retention volume of the solvent front (amount of the mobile phase in the column), and  $V_C$  the total column capacity.

### Retention of Stationary Phase

The retention of the stationary phase in the separation column is an important parameter to determine the resolution of solute peaks in CCC. Generally, the higher the retention of the stationary phase, the better the separation. In the hydrostatic systems, the retention of the stationary phase is improved simply by reducing the flow rate of the mobile phase.

In the hydrodynamic systems, which provide efficient mixing of the two phases, the retention of the stationary phase depends on the physical properties of the two-phase solvent system as well as the choice of the mobile phase and its elution mode. In HSCCC using the type-J planetary motion, the settling time of the two solvent phases in unit gravity provides a useful measure for the retention of the stationary phase and the elution mode. The test is performed as follows: the two phases are pre-equilibrated in a separating funnel and 2 ml of each phase is delivered into a 5 ml graduated cylinder equipped with a

stopper (an ordinary glass test tube of 13 mm OD and 10 cm length with a polyethylene cap can also be used). The contents are gently mixed by inverting the container five times and the time required to form two clear layers is measured. If this settling time is within 30 s, the solvent system can be used for separation by eluting the lower phase from the head toward the tail or the upper phase in the reversed mode. If the settling time exceeds 30 s, the above elution mode should be reversed while the retention of the stationary phase is usually considerably lower than an optimum range. However, this settling time test is not applied to the cross-axis coil planet centrifuges. These centrifuge systems provide excellent retention of the stationary phase for almost all two-phase solvent systems including viscous polymer phase systems used for partition of macromolecules and cell particles.

### CCC versus HPLC

CCC is a pure liquid-liquid partition chromatographic method using no solid support and has various advantages over HPLC. Although both methods are based on the same principle of solute partitioning between two phases, HPLC uses a bulk of solid support coated with the thin film of stationary phase, which limits the amount of stationary phase and its sample loading capacity. In contrast, CCC uses an empty column filled with a liquid stationary phase. When eluted with the mobile phase, the column can still retain over 50% of the stationary phase and therefore it has a large sample loading capacity. The solid support used in HPLC often irreversibly adsorbs the solutes and denatures the proteins. Solid support preparation is difficult to control, expensive, and often unstable. Most importantly, CCC separations are predictable. From the partition coefficient that is measured by a simple test tube experiment, one can predict the retention time of the target compounds.

### Introduction

Three steps required for multistage solvent extraction, i.e., phase mixing, phase settling, and transfer of the mobile phase, are defined clearly in the discontinuous countercurrent distribution process using the Craig apparatus. These basic requirements are essentially fulfilled by the use of a coiled tube in a continuous fashion. Solvent extraction using a coiled column is most efficiently performed with a horizontally laid coil that rotates about its own axis. In this horizontal coil orientation, the rotation induces the well known Archimedean screw force, which can be utilized for performing countercurrent solvent extraction.

### Hydrodynamic Motion of Two Immiscible Solvent Phases in a Rotating Coil

This Archimedean screw effect on the hydrodynamic distribution of the solvent phases is illustrated in **Figure 1**, where each coil, consisting of five helical turns, is placed horizontally and rotated slowly around its axis. In **Figure 1A**, air bubbles and glass beads are introduced in the coil, previously filled with water, and both ends of the coil are sealed. Then, rotation of the coil in the indicated direction induces an Archimedean screw force that drives all the suspended objects (lighter or heavier than the

### Introduction

Three steps required for multistage solvent extraction, i.e., phase mixing, phase settling, and transfer of the mobile phase, are defined clearly in the discontinuous countercurrent distribution process using the Craig apparatus. These basic requirements are essentially fulfilled by the use of a coiled tube in a continuous fashion. Solvent extraction using a coiled column is most efficiently performed with a horizontally laid coil that rotates about its own axis. In this horizontal coil orientation, the rotation induces the well known Archimedean screw force, which can be utilized for performing countercurrent solvent extraction.

### Hydrodynamic Motion of Two Immiscible Solvent Phases in a Rotating Coil

This Archimedean screw effect on the hydrodynamic distribution of the solvent phases is illustrated in **Figure 1**, where each coil, consisting of five helical turns, is placed horizontally and rotated slowly around its axis. In **Figure 1A**, air bubbles and glass beads are introduced in the coil, previously filled with water, and both ends of the coil are sealed. Then, rotation of the coil in the indicated direction induces an Archimedean screw force that drives all the suspended objects (lighter or heavier than the

**Figure 1** Archimedean screw effect in a rotating coil. (A) Motion of air bubbles and glass beads suspended in water; (B) Motion of droplets of one phase of an equilibrated two-phase solvent system suspended in the other phase; (C) Hydrodynamic equilibrium of two immiscible solvent phases in a slowly rotating coil.

water) toward the end of the coil labeled 'head' (the other side of the coil is called the 'tail'). Under a slow coil rotation, the air bubbles (which are lighter than the water) always stay at the top of the coil, while the

glass beads (which are heavier than the water) stay at the bottom of the coil, both moving toward the head of the coil at a rate of one helical turn per rotation of the coil. Finally, both air bubbles and glass beads reach the head of the coil, where they remain by repeating a back and forth motion synchronous with the rotation of the coil.

In **Figure 1B**, similar experiments are performed with a two-phase solvent system. The first coil is filled with the lighter phase (white) of an equilibrated two-phase solvent system, and a small amount of the heavier phase (black) is added. Then, under a slow rotation of the coil, droplets of the heavier phase remain at the bottom of the coil, traveling through the coil at a rate equal to the coil rotation. Similarly, the second coil is filled with the heavier phase (black), and a small amount of the lighter phase (white) is added. Under a slow rotation, droplets of the lighter phase stay at the top of the coil, again traveling toward the head of the coil at a rate of one turn per rotation of the coil.

In **Figure 1C**, the coil is filled with nearly equal volumes of the two phases and rotated slowly about its axis. In this case, the lighter phase stays at the upper portion and the heavier phase at the lower portion of the coil, both competitively advancing toward the head of the coil. Sooner or later, the two phases establish a hydrodynamic equilibrium where each phase occupies about an equal space on the head side of the coil, and any excess of either phase remains at the tail end of the coil. Once this hydrodynamic equilibrium is formed, continued rotation of the coil mixes the two solvent phases vigorously, while the overall distribution of the two phases remains unaltered.

This hydrodynamic equilibrium can be used for performing solute extraction in the following manner: The coil is first filled entirely with the stationary phase, either the lighter or the heavier phase, and the sample solution dissolved in either phase is introduced at the head side of the coil. Then, the mobile phase is eluted through the coil from the head toward the tail while the coil is slowly rotated around its axis. As the mobile phase meets the stationary phase in the rotating coil, the two solvent phases establish a hydrodynamic equilibrium quickly: the two phases are vigorously mixed by rotation of the coil, while some amount of the stationary phase is permanently retained in the coil. This process continues in each helical turn of the coil. After the entire coil attains a hydrodynamic equilibrium state and the mobile phase begins to elute from the tail end of the coil, the mobile phase only displaces the same phase in the coil, leaving the retained stationary phase permanently in the coil. Consequently, the solutes present

in the sample solution are subjected to an efficient partition process as in the multistage countercurrent distribution with the Craig apparatus but in a continuous manner.

The partition efficiency in this partition system is highly dependent upon the amount of the stationary phase retained in the column. Under a slow rotation of the coil as described above, the two solvent phases occupy competitively the head side of the coil where the elution of either phase from the head of the coil only permits retention of the stationary phase at a maximum level of 50% of the column capacity. It has been found, however, that the volume ratio of the two phases occupying the head side of the coil can be altered by increasing the rotation speed of the coil.

In **Figure 2**, three diagrams indicate the effect of rotation speed on the two-phase distribution on the head side of the coil. The experiments were performed using a set of coils with helical diameters of 3, 10, and 20 cm as indicated on the left. Each coil was first filled with about equal volumes of the lighter and heavier phases of chloroform/acetic acid/0.1 mol l<sup>-1</sup> hydrochloric acid (2:2:1, v/v), closed at both ends, and then rotated at the desired speed. After a hydrodynamic phase equilibrium was reached, the rotation was stopped and the volume of the two phases occupying head side of the coil was measured. The percentage volume of the heavier (lower) phase occupying the head of the coil was then plotted against the rotation speed of the coil.

The three diagrams obtained from different helical diameters show common features: In the slow rotation speed, between 0 rpm and 30 rpm, the two solvent phases distribute fairly evenly in the coil (stage I). When the rotation speed is increased, the heavier nonaqueous phase tends to occupy more space on the head side of the coil, and at a critical speed between 60 rpm and 100 rpm, the two phases are almost completely separated along the length of the coil, the heavier phase occupying the head side and the lighter phase the tail side of the coil (stage II). This particular two-phase distribution is called bilateral and most efficiently utilized for performing solvent extraction. After this critical speed range, the amount of heavier phase on the head side tends to decrease rather sharply, crossing below the 50% line (stage III). A further increase in the rotational speed again yields an even distribution of the two phases in the coil (stage IV). As the helical diameter increases, all these stages tend to shift toward the lower rpm range, apparently due to the enhanced centrifugal force field.

Series of similar studies have been carried out using various two-phase solvent systems with a broad spectrum of hydrophobicity. **Figure 3** illustrates a set

**Figure 2** Hydrodynamic distribution of a two-phase solvent system composed of chloroform/acetic acid/0.1 mol l<sup>-1</sup> hydrochloric acid (2:2:1, v/v) in rotating coils of three different helical diameters, shown on the left.

of phase distribution diagrams obtained from nine commonly used volatile solvent systems in glass coils of various sizes with or without a silicone coating. These diagrams are arranged from left to right in the order of hydrophobicity of the major organic solvents as labeled at the top of each column, whereas the inner diameter (ID) and core diameter of the coils are indicated on the left margin. In each diagram the solid curve was obtained from an untreated coil and the broken curve from the same coil after silicone coating. Thus, any difference between these two curves indicates the effects of the solvent-wall interaction. An absence of one or both distribution curves in the designated space indicates that the two solvent phases failed to move or displayed sluggish motion in the coil and, therefore, the measurement could not be completed. These data indicate that with only a few exceptions, various two-phase solvent systems establish a bilateral hydrodynamic distribution in 1–2 cm ID coils at rotation speeds ~100 rpm.

## Mechanism of Countercurrent Extraction

As mentioned above, the bilateral hydrodynamic distribution of the two phases can be utilized efficiently

for performing solvent extraction. **Figure 4** illustrates schematically the hydrodynamic mechanisms in solvent extraction using the basic hydrodynamic distribution (stage I) under a slow coil rotation (left) and the bilateral hydrodynamic distribution (stage II) at the critical rotation speed (right). For simplicity, all rotating coils – except for one shown at the top – are drawn uncoiled to show the overall distribution of the two solvent phases along the length of the coil.

In the basic hydrodynamic equilibrium system (left), the slow rotation of the coil distributes the two phases evenly from the head of the coil (top). In order to obtain retention of the stationary phase in the coil under this hydrodynamic condition, the mobile phase, regardless of whether it is the heavier or lighter phase, should be introduced from the head of the coil. This operation results in a low level of stationary phase retention, usually much less than 50% of the total column capacity, as shown in the diagram. Elution of either phase from the tail of the coil would result in a total loss of the stationary phase from the coil.

In the bilateral hydrodynamic equilibrium system (right), the critical rotation speed distributes the two phases bilaterally along the length of the coil, the head phase (white) entirely occupying the head side and the tail phase (gray) the tail side of the coil as

**Figure 3** Phase distribution diagrams for nine volatile two-phase solvent systems obtained from glass coils with various dimensions, as indicated on the left. The solid curve indicates the data obtained from nontreated glass coils and the dotted curve, from silicone-treated glass coils. The thin vertical line in each diagram indicates the rpm value at which the centrifugal force field created by the rotation equals unit gravity. Note that most solvent systems exhibit the critical rpm value where one phase occupies 100% of the column space on the head side of the coil.

**Figure 4** Mechanism of solvent extraction with rotating coils. Left: basic hydrodynamic distribution produced by a slow coil rotation (stage I). Right: bilateral hydrodynamic distribution produced by the critical rotation speed (stage II).

shown in the first coil. In a rotating coil under unit gravity, the heavier phase usually becomes the head phase (see Figure 3). This hydrodynamic equilibrium condition indicates clearly that the tail phase, if

introduced at the head end of the coil, would travel through the head phase toward the tail and that the head phase, if introduced at the tail end of the coil, would travel through the tail phase toward the head.

This hydrodynamic trend is effectively utilized for performing the solvent extraction in two different manners: The tail phase is eluted from the head toward the tail of the coil, previously filled with the head phase. Alternatively, the head phase is eluted from the tail toward the head of the coil, previously filled with the tail phase. In either case, the mobile phase can travel quickly through the coil, leaving a large volume of the stationary phase in the coil.

This bilateral hydrodynamic system also permits simultaneous elution of the two solvent phases through the respective ends of the coil as shown at the bottom of the diagram. This dual countercurrent operation requires an additional flow tube at each end of the coil to collect the effluent and, if desired, a sample feed tube at the middle portion of the coil for continuous sample feeding.

Comparison of the above two hydrodynamic systems reveals that the bilateral hydrodynamic system (Figure 4, right) provides several advantages over the basic hydrodynamic system (Figure 4, left): the bilateral system gives a better retention of the stationary phase in the column and yields a higher partition efficiency in a given period of time due to more efficient phase mixing under a higher rotation speed of the coil. The system can also be applied to dual countercurrent operation, where the two solvent phases literally undergo countercurrent movement through a coiled column.

## Apparatus for Solvent Extraction

Three different types extraction instrument based on the bilateral hydrodynamic equilibrium are used: a slow rotary countercurrent apparatus (Figure 5) and two types of high-speed centrifuge systems, one for standard extraction (Figure 6) and the other for dual countercurrent extraction, with a spiral column

(Figure 7). All these instruments are free of rotary seals.

### Slow Rotary Countercurrent Chromatography Apparatus

The slow rotary countercurrent chromatography (CCC) apparatus holds a long column holder, which slowly rotates about its axis (Figure 5). The separation column is prepared by winding a long Teflon tube directly onto the holder hub, making multiple coiled layers. Two types of Teflon tube were used, standard tubing and convoluted tubing (similar to a miniature vacuum cleaner duct). A pair of flow tubes from each terminal is passed through the hole of the hollow central shaft and then making an arch supported by a lateral tube support and then exiting the centrifuge system through another hole on the central shaft.

The motor drives the rotary frame around the central axis of the centrifuge. Because the pulley at the right end of the countershaft is engaged to the stationary pulley with a toothed belt, the countershaft counter-rotates at the same rate on the rotating rotary frame. This motion is further conveyed to the column holder by a 1:1 gear coupling between the countershaft and the column holder. Consequently, the column holder rotates at the doubled speed with respect to the earth. This system allows the flow tubes to rotate without twisting, thus eliminating the need for rotary seals, and the high-speed centrifuge based on this rotary-seal-free system is widely used for apheresis at blood banks.

### Standard High-Speed CCC System

The multilayer coil assembly described above utilizes the Archimedean screw effect produced by the unit gravity. Thus, the relatively weak gravitational field limits the efficiency of the system. It has been found that the use of a centrifugal force field enhances the

**Figure 5** Cross-sectional view of seal-free slow rotary countercurrent chromatography (CCC) equipped with a large multilayer coil.

**Figure 6** Cross-sectional view of the coil planet centrifuge used for solvent extraction. One column holder (bottom) holds a coiled column, while the other (top) serves as a counterbalance.

partition efficiency in terms of both theoretical plate and the elution time.

Among various coil planet centrifuge systems developed in the 1980s and 1990s, the type-J synchronous system produces a particular mode of planetary motion that yields a bilateral hydrodynamic equilibrium of two solvent phases in a multilayer coil mounted coaxially around the holder. Consequently, the system is applied efficiently to both solvent extraction and CCC.

A cross-sectional view of the type-J coil planet centrifuge is illustrated in **Figure 6**. The motor (left,

bottom) drives the rotary frame via a pair of toothed pulleys and a toothed belt. The rotary frame holds a pair of column holders in symmetrical positions at a distance of 10 cm from the centrifuge axis. Each holder is equipped with a planetary gear that is engaged to an identical stationary sun gear (shaded) mounted rigidly around the central stationary pipe (shaded). This gear arrangement produces a planetary motion synchronous with the holder, i.e., one rotation about its own axis for each revolution around the central axis of the centrifuge in the same direction. A single-layer coiled column was mounted

**Figure 7** Instrumentation of dual countercurrent chromatograph. (A) Design of the spiral disk; (B) cross-sectional view of the apparatus.

around one column holder (lower), and the other holder (upper) served to counterbalance the centrifuge system. A pair of flow tubes from the separation coil first passes through the center hole on the holder shaft and then, by making an arch, reaches the side hole made on the short coupling pipe to enter the opening of the central stationary pipe. As mentioned elsewhere these tubes are not twisted during a centrifuge run.

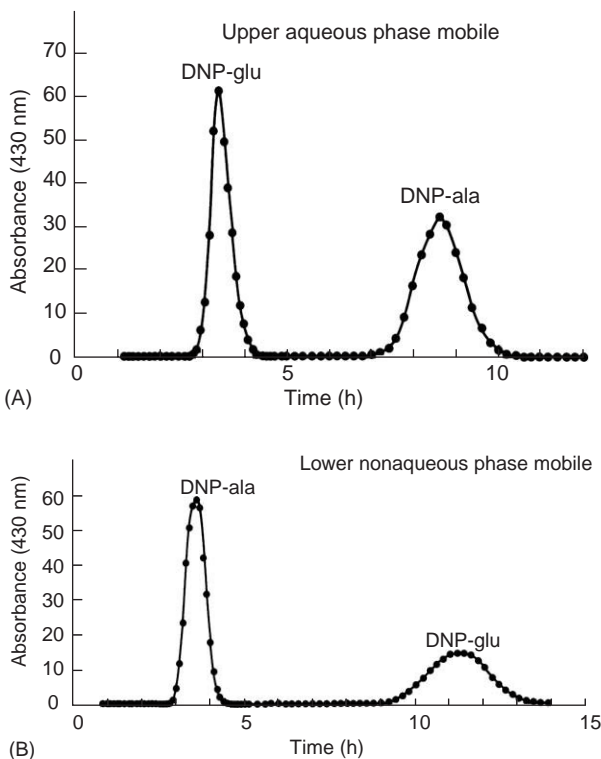

### Spiral Disk Dual Countercurrent Extraction Centrifuge

Figure 7 illustrates the new dual countercurrent extraction system (see Figure 4) using a spiral disk (A) mounted on the type-J synchronous planetary centrifuge system (B). The use of spiral channel configuration generates a radial centrifugal force gradient, enhancing the countercurrent movement of the two phases. This instrument is designed for separation of small amounts of pesticide in vegetable oil for mass spectrometric analysis. Because there is no stationary phase, multiple sample injections at regular intervals become possible without a risk of depleting the stationary phase or accumulating extracted oil, which would occur in the multilayer coil in the standard high-speed CCC technique.

### Solvent Extraction with a Rotating Coil in a Unit Gravity

Hydrodynamic studies (Figure 2) using the three coiled columns, with helical diameters ranging from 3 cm to 20 cm, demonstrated that the bilateral hydrodynamic distribution is established in all these coils  $\sim 100$  rpm. This result indicates that a long coiled column can be fabricated compactly by winding a single piece of plastic tubing around a spool-shaped rotary drum, making multiple coiled layers with dimensions as large as a 20 cm outside diameter (OD). The performance of this bilateral hydrodynamic extraction system in separating 2,4-dinitrophenyl (DNP) amino acids in a two-phase solvent system composed of chloroform, glacial acetic acid, and  $0.1 \text{ mol l}^{-1}$  hydrochloric acid at a volume ratio of 2:2:1 was examined. A large capacity multilayer coil was fabricated from a 30 m long, 5.5 mm ID fluorinated ethylene propylene (FEP) tube by winding it coaxially onto a 10 cm diameter, 25 cm wide spool support, making three layers of the coil with a total capacity of  $\sim 750$  ml.

Figure 8 shows the results of this preliminary separation, where both upper (A) and lower (B) phases were used as the mobile phase. In both separations two DNP amino acids are well resolved and eluted

**Figure 8** Separation of DNP amino acids with a multilayer coil rotating in a unit gravity. Column: multilayer coil, 30 m long, 5.5 mm ID FEP tube with capacity 750 ml. Sample: DNP-glu and DNP-ala, 500 mg of each dissolved in 30 ml of solvent. Solvent system: chloroform/glacial acetic acid/ $0.1 \text{ mol l}^{-1}$  hydrochloric acid (2:2:1, v/v). Mobile phase: lighter aqueous phase (A) and heavier nonaqueous phase (B). Flow rate:  $516 \text{ ml h}^{-1}$ . Coil rotation: 80 rpm.

out as symmetrical peaks. The partition efficiency, expressed in terms of the theoretical plate number, is over 200, which is nearly equivalent to that obtained from 200 partition units in the Craig countercurrent distribution apparatus. This method can be applied to extraction or separation of various compounds using suitable two-phase solvent systems.

This slow rotary countercurrent extraction system has been applied for a large scale preparative separation of natural products using a multilayer coil prepared from convoluted PTFE tubing as shown in Figure 9. About 150 g amount of crude tea leaf extract was separated into four components in 72 h. In this separation, over 40 g of epigallocatechin gallate (EGCG) (fourth peak) was obtained at a high purity of 92.7%. The convoluted tubing provides some advantages over the standard tubing, such as ease of coil preparation and higher retention of the organic stationary phase.

This low-speed rotary coil extraction system has various desirable features for industrial applications: the sample loading capacity can be scaled up simply by increasing the diameter of the multilayer coil

**Figure 9** Separation of crude extract of tea leaves using low-speed countercurrent extraction apparatus equipped with a multilayer coil of convoluted tubing. Column: multilayer coil made of convoluted PTFE tubing, 200 m long, 8.5 mm average ID coiled  $\sim 9$  cm OD holder hub, forming seven layers, each consisting of 60 loops with a total capacity of 10 l (see **Figure 5**). Sample: 150 g of tea leaf extract dissolved in 1.2 l of solvent consisting of equal volumes of each phase. Solvent system: *n*-hexane/ethyl acetate/*n*-butanol/acetic acid/water (0.5:1:2:0.2:6, v/v). Mobile phase: lower aqueous phase. Elution mode: head to tail. Flow rate: 5 ml min<sup>-1</sup>. Column rotation: 21 rpm. Retention of the stationary phase: 33%.

and/or the width of the coil holder. The system also provides excellent safety features such as low rotation speed, low column pressure, and minimum risk of leakage of the solvent. Because of its simplicity, the system may be automated easily for long-term operation.

## Solvent Extraction with a Coil Planet Centrifuge

### Extraction of DNP Amino Acids

Continuous countercurrent extraction is efficiently performed using the high-speed coil planet centrifuge as shown in **Figure 6**. It enables extraction of a solute present in a large volume of the mobile phase into a small volume of the stationary phase retained in the coiled column. This requires a set of conditions such that the solute must favor partition to the stationary phase. With commonly used extraction media such as an ethyl acetate–aqueous system, partition coefficients of various biological materials can be adjusted conveniently by modifying the pH and/or ionic strength of the aqueous phase to meet the above requirement. For the model studies, a pair of DNP-amino acids, *N*-2,4-DNP-L-leucine (DNP-leu) and  $\delta$ -*N*-2,4-DNP-L-ornithine (DNP-orn), were selected as samples because they are readily observed through the column wall during the extraction process under stroboscopic illumination and also provide suitable partition coefficients.

A typical extraction procedure may be divided into three steps, i.e., extraction, cleaning, and collection. In each operation, the column was filled with the stationary phase and the mobile phase containing the

sample was eluted through the column in the proper direction while the apparatus was run at 600 rpm. The extraction process was continued until 400 ml of the mobile phase was eluted. Then the mobile phase was replaced by the same phase but free of solute to wash the column contents. This cleaning process was continued until the additional 100 ml of the mobile phase was eluted. This would elute out all impurities having a partition coefficient of 0.1 or greater. The sample extracted into the stationary phase in the coiled column was collected by eluting with the mobile phase in the opposite direction. The sample still remaining in the column was then washed out by eluting the column with the other phase originally used as the stationary phase. The degree of sample recovery was estimated by comparing the amount of the sample in the original mobile phase with that in the collected stationary phase.

The results of the experiments are summarized in **Table 1**. In experiments 1–3, DNP-leu dissolved in the aqueous mobile phase was extracted into  $\sim 10$  ml of the stationary nonaqueous phase. The sample recovery ranges from 94% to 100%. In experiments 4 and 5, DNP-orn dissolved in the nonaqueous mobile phase was extracted into the aqueous stationary phase. The sample recovery was in the range 97–100%. In practice, application of the method to aqueous crude extracts or physiological fluids requires a preliminary adjustment of the solvent composition for providing a suitable partition coefficient of the desired material for the applied pair of solvents. In this case, pre-equilibration of the two phases may not be essential. Experiment 6 shows an example of operation with such nonequilibrated solvents. The sample DNP-leu was first dissolved in

**Table 1** Experimental conditions and results of extraction

Exp. no.	Solvent system	Mobile phase	Stationary phase	Sample (P.C.) <sup>a</sup>	Sample conc. in mobile phase (mg%)	Extracted mobile phase volume (ml)	Flow rate (direction)	RPM	Collected stationary phase volume (ml)	Sample recovery (%)

6	Nonequilibrium system	5% Ethylacetate in 0.5 mol NaH <sub>2</sub> PO <sub>4</sub>	Ethylacetate	DNP-leu ( $<0.01$ )	0.4	400	516 ml h <sup>-1</sup> (Head-tail)	600	6.1	99

<sup>a</sup> Partition coefficient is defined as solute concentration in the mobile phase divided by that in the stationary phase.

400 ml of 0.5 mol l<sup>-1</sup> NaH<sub>2</sub>PO<sub>4</sub> aqueous solution containing ethyl acetate at 5%, which is slightly below the saturation level of ~7%. The column was filled with ethyl acetate followed by elution with the above sample solution. Both extraction and cleaning processes were performed as in other experiments. The sample solution collected from the column measured slightly over 6 ml. This depletion of the stationary phase resulted apparently from use of the nonequilibrated solvent pair but without any effect on the sample recovery.

The overall results indicate the potential usefulness of the present method in processing large amounts of crude extracts or biological fluids in research laboratories. A small amount of the sample present in several hundred milliliters of the original solution can be enriched in 10 ml of the nonaqueous phase free of salt in 1 h, at a high recovery rate.

### Extraction of Urinary Drug Metabolites

The present method has been applied to extraction of urinary metabolites of daunorubicin, an anticancer drug. The extraction was performed with a two-phase solvent system composed of *n*-butanol/0.3 mol l<sup>-1</sup> Na<sub>2</sub>HPO<sub>4</sub>. Prior to the extraction, the urine sample was saturated with *n*-butanol, and then Na<sub>2</sub>HPO<sub>4</sub> was added at a concentration of 0.3 mol l<sup>-1</sup>. In each experiment, the column was first filled with *n*-butanol. Then, the apparatus was rotated at 650 rpm while aqueous Na<sub>2</sub>HPO<sub>4</sub> saturated with *n*-butanol was pumped into the column to equilibrate the stationary phase. The prepared urine sample, 1–2 l in volume, was then eluted through the column at a flow rate of 500–700 ml h<sup>-1</sup> with a metering pump. After all the sample solution was eluted, the column was cleaned by eluting with 100 ml of aqueous, *n*-butanol-saturated 0.3 mol l<sup>-1</sup> Na<sub>2</sub>HPO<sub>4</sub>. Then, the centrifuge run was terminated and the retained *n*-butanol phase was drained from the column by connecting the column inlet to an N<sub>2</sub> line under pressure. Several milliliters of *n*-butanol were flushed through the column to recover any remaining sample. The *n*-butanol extracts were combined and evaporated to dryness by flash evaporation.

The results of the experiments are illustrated in Figure 10, where the high-performance liquid chromatography (HPLC) analysis of the original urine sample and that of the countercurrent extract are compared. In Figure 10A, the chromatogram of the original urine sample shows a large amount of hydrophilic material at the solvent front and two metabolites peaks, D<sub>1</sub> and D<sub>2</sub>. As shown in Figure 10B, the chromatogram of the countercurrent extract with the coil planet centrifuge reveals enriched D<sub>1</sub> and D<sub>2</sub>

**Figure 10** Extraction of urinary metabolites of daunorubicin using the coil planet centrifuge. (A) HPLC analysis of the original urine; (B) HPLC analysis of the countercurrent extract.

peaks and three additional metabolite peaks, dD<sub>3</sub>, demethyl-dD<sub>3</sub>, and 4-O-glucuronide as indicated in the chromatogram.

## DERIVATIZATION OF ANALYTES

**S Görög**, Chemical Works of Gedeon Richter Ltd., Budapest, Hungary

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The derivatization of analytes is very important in several branches of analytical chemistry. It expands the fields of application of various spectroscopic techniques (ultraviolet-visible (UV-vis), fluorimetry, nuclear magnetic resonance (NMR), and mass spectroscopies), and in several cases increases also the selectivity and sensitivity of these techniques. Derivatization is also an inevitable tool in all chromatographic and electrophoretic techniques. In gas chromatography (GC), the main importance of derivatization is the improvement of the volatility/thermal stability of the analytes, and in all of the discussed separation techniques it has the potential of increasing the selectivity of the separation (including enantiomeric separations) and the sensitivity of the detection.

### Definition: Historical Background

In a broad sense, all chemical transformations of the analyte taking place in the course of an analytical procedure can be considered to be derivatization reactions. These methods can be classified as follows:

1. Practically all kinds of classical analytical procedures (acid-base, redox, precipitation, and complexometric titrations as well as gravimetry) fall into this category. An example from the field of titrations is the transformation of acetylsalicylic acid to sodium acetylsalicylate with sodium hydroxide as the titrant, or to sodium salicylate and sodium acetate if the method is based on the

hydrolysis of the ester group in the analyte followed by titration of excess sodium hydroxide with hydrochloric acid. Further examples are the reduction of iron(III) to iron(II) with iodide ions in the course of its iodometric determination, the precipitation reaction between chloride and silver ions taking place during the determination of chloride, or the transformation of a wide range of metal ions to the ethylenediamine tetraacetate complexes during their complexometric determination. Examples for gravimetric assays are the determination of sulfate after transformation to barium sulfate and determination of various aldehydes and ketones after their transformation to the 2,4-dinitrophenylhydrazones. The discussion of these classical reactions will not be the subject of this article.

2. After the introduction of instrumental analytical methods several possibilities became available where no chemical reactions were involved in the complex analytical procedure. Methods of this kind are various spectroscopic and spectrophotometric methods, GC with thermal conductivity or electron-capture detector, high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE) with UV or fluorimetric detector, etc. In other cases chemical reaction takes place in the detector of the instruments as a step of the complex procedure leading to the analytical signal. Examples are the combustion of the analyte in the flame ionization detector of gas chromatographs, their oxidation, reduction, or other transformation in various electrochemical sensors and detectors, fragmentation of the molecules in mass spectrometers, etc. These reactions will also not be discussed in this article.
3. Derivatization in the up-to-date sense of the word is the transformation of the analyte by a chemical

reaction to a modified structure either outside or inside the analytical instrument prior to the formation of the analytical signal with the aim of expanding the application field of the analytical method to the analyte or increasing the selectivity or the sensitivity of the method. Chemical derivatization is not restricted to the formation of covalent bonds: the formation of ion pairs, complexes, and adducts that can greatly improve the selectivity of various analytical methods can also be considered to be derivatization reactions. These reactions – leading to covalently and noncovalently bound derivatives alike – will be the subject of this article. (Note: a widely accepted criterion of a derivatization reaction in analytical chemistry is that the molecule of the analyte is transformed to a larger, more complex molecule. This is, however, not applicable in all cases: reduction of ketones to hydroxyl derivatives, oxidation of the latter to ketones, acid-catalyzed elimination of water or carboxylic acids to form (conjugated) double bonds, hydrolysis of esters, etc., can also be considered to be (retro)-derivatization reactions.)

## Spectroscopic and Spectrophotometric Techniques

### UV-Visible Spectrophotometry

Although UV-vis spectrophotometers were already available in the 1910s, their use was limited to a few laboratories only. However, filter photometers operating only in the visible spectral region found wide-ranging applications. Thus, it was the precondition of their application to colorless compounds that the analytes were converted to colored derivatives prior to the measurement. Innumerable methods were developed in the following decades based on this principle with sometimes well established but in many cases obscure chemical background. After the spread of UV-vis spectrophotometers in the middle of the twentieth century the importance of these methods decreased considerably, but spectrophotometric/colorimetric methods based on chemical reactions have retained some importance among others in the field of metal and pharmaceutical analysis up to the present time. The reasons for this are that this is the only possibility for the spectrophotometric determination of UV-inactive materials in the form of UV-active or colored derivatives, the selectivity and sensitivity can often be increased by the formation of spectrophotometrically highly active derivatives ( $\epsilon \sim 10\,000\text{--}50\,000\text{ l mol}^{-1}\text{ cm}^{-1}$ ), and the transformation of analyte to colored derivatives is often the prerequisite of using automatic analyzers equipped

with inexpensive filter photometers mainly in the clinical analytical practice.

Some examples are the determination of iron(II) as the 2,2'-dipyridyl or 1,10-phenanthroline complex, iron(III) in the form of the thiocyanate complex, various metals (e.g., Cu(II), Ag(I), Pb(II), Zn(II), and Hg(II)) in the form of dithizone complexes, etc. (The formation of colored derivatives of metal ions with various reagents is useful in their determination by ion chromatography with a UV-vis detector.) Of the pharmaceutical applications that are still in use, typical examples are the determination of drugs with suitable functional groups after chelation reaction with various metal ions; e.g., the determination of salicylic acid impurity in acetylsalicylic acid as its complex with iron(III), determination of alkaloids and other basic materials after ion-pair formation with various acidic dyes, diazotization and azo coupling for the determination of aromatic amines and phenols, condensation of 4-ene-3-oxosteroids with isonicotinoyl hydrazine, indirect determination of corticosteroids with reducing  $\alpha$ -ketol-type side chain using tetrazolium reagents. Enzymatic reactions excel due to their high specificity. An example is the determination of paracetamol (4-acetaminophenol) in serum based on enzymatic hydrolysis to 4-aminophenol followed by oxidative coupling with *o*-cresol to form a colored indophenol derivative.

A more up-to-date application field of UV-vis spectrophotometry is flow injection analysis where the spectrophotometer is the generally used detector. In this technique, the sample and the reagent(s) are injected into a continuous, unsegmented flow produced by a pump. The reaction takes place in a temperature-controlled reaction coil, and the reaction product producing sharp peaks is measured in the detector.

### Fluorimetry

Compounds not having (sufficiently intense) native fluorescence can be transformed with suitable reagents to fluorescent derivatives enabling high sensitivity to be obtained in the course of their fluorimetric determination.

Two general types of these reactions can be mentioned:

1. The structure of the analyte is changed to a fluorescent derivative by inorganic reagents, mainly oxidizing agents. For example, morphine is oxidized by ferricyanide reagent to pseudomorphine, enabling its highly sensitive and selective determination in the presence of related derivatives such as codeine, dihydromorphine, diacetylmorphine, and apomorphine. Similarly, selective and sensitive determination is obtainable when vitamin B<sub>1</sub>

(thiamine) is oxidized with the same reagent to the highly fluorescent thiochrome derivative.

2. More general is the applicability of the other type of reactions where any kind of molecules with suitable functional groups can be transformed to highly fluorescent derivatives by means of a derivatization reaction with suitable fluorescent reagents. In the majority of cases the fluorescence of the excess reagent excludes the possibility of the direct determination of the derivatized analyte. These derivatization reactions are useful tools for the determination of various compounds by HPLC using fluorescence detection. This explains why at present much attention is devoted to the development of fluorogenic derivatizations in which the reagent is not fluorescent itself while the derivative exerts strong fluorescence. A classical example is fluorescamine, which is suitable for the very sensitive determination of primary amines (see Scheme 1).

Time-resolved fluorimetry, a modern variant of fluorimetry, excels with its high specificity. This technique is based on the derivatization reaction of various compounds with europium(III) to form highly fluorescent chelates with extremely long decay time. Using a suitable instrument the long decay time enables the long-lived fluorescence of the derivatized analyte to be resolved from the short-lived fluorescence of the background and interfering components in biological samples.

### NMR Spectroscopy

Hydrogen–deuterium exchange taking place between labile protons (e.g., OH–, NH–, COOH–, or acidic CH) of the analyte and deuterated solvents (D<sub>2</sub>O, CD<sub>3</sub>OD, CF<sub>3</sub>COOD, etc.) can be considered a simple derivatization reaction. This is a very useful tool in the assignment of signals in the respective groups and environments and is therefore part of the everyday routine both in <sup>1</sup>H and <sup>13</sup>C NMR spectroscopies. Further possibilities are also available for NMR spectroscopists, based on complex or adduct formation, to solve a wide variety of problems ranging

from signal assignment through the determination of absolute configuration of the analyte to the investigation of its molecular dynamic properties. In addition to the classical shift reagent Eu(acetylacetonate)<sub>3</sub> complex and others, chiral shift reagents (where the ligand of the Eu<sup>3+</sup> complex is an enantiomerically pure chiral compound) and especially cyclodextrins are extremely useful tools in estimating enantiomer excess or even enantiomeric purity of chiral compounds.

### Mass Spectrometry

See sections ‘Gas chromatography and GC–MS’ and ‘High-performance liquid chromatography and LC–MS’.

## Chromatographic and Electrophoretic Techniques

### Thin-Layer Chromatography

Although (*in situ*) prechromatographic derivatization of the analytes in thin-layer chromatography (TLC) has been described in several cases, much more important are the postchromatographic reactions with various reagents.

The aim of postchromatographic derivatization is to make the separated compounds visible at daylight or to transform them to fluorescent derivatives, thus enabling primarily the sensitivity and often also the selectivity of the detection and of the densitometric determination to be increased.

There are several modes to expose the separated compounds to the reagent. Of the vapor-phase reagents only iodine vapor is widely used. The incorporation of the reagent in the mobile or stationary phases has been reported only in a limited number of cases. The two main techniques are spraying the plate with relatively concentrated reagent solutions and dipping it into less concentrated solutions.

Some of the innumerable reagents used in TLC are based on reactions with more or less well-established mechanism. For example, sodium iodobismuthate (Dragendorff reagent) is widely used among others for alkaloids and quaternary ammonium compounds, 4-dimethylaminobenzaldehyde for primary amines and amino acids, 2,4-dinitrophenylhydrazine for aldehydes and ketones, ninhydrin for amino acids and some antibiotics, fluorescamine for primary and secondary amines, phosphomolybdic acid for lipids, various steroids, and other compounds, chlorine vapor followed by KI/starch for amines and amides. More complex is the mechanism of the reactions with some other reagents, containing high concentrations of sulfuric acid, vanillin/sulfuric acid, phosphoric acid, aluminum chloride, antimony(III)

Scheme 1

chloride, etc., which produce various colors and fluorescence upon heating the plate in the course of the analysis of various classes of organic compounds, e.g., steroids.

### Gas Chromatography and GC-MS

Although many organic compounds can be chromatographed in the gas phase without derivatization, it still plays an important role here also. The aim of derivatization prior to the GC-MS analysis is

- expanding the capabilities of GC by blocking the polar functional groups in the analytes, thus enabling compounds that are not sufficiently volatile to be analyzed;
- improving the peak shape of polar compounds;
- improving the sensitivity of the detection and quantitation; and
- improving the selectivity by enabling the separation of compounds that are not sufficiently separated in the underivatized form.

The most frequently derivatized functional groups are hydroxy, carboxy, and amino groups.

**Derivatization of hydroxy compounds** The most widely used derivatization reaction is their transformation to silyl (in the majority of cases trimethylsilyl) ether derivatives. Hexamethyldisilazane is the classical and still widely used silylating agent (usually mixed with trimethylchlorosilane, which is the catalyst generally used for various silylation reactions). For less reactive (sterically hindered) hydroxy groups more reactive reagents (*N,O*-bis(trimethylsilyl)acetamide, *N,O*-bis(trimethylsilyl)trifluoroacetamide, *N*-methyl-*N*-trimethylsilyltrifluoroacetamide, trimethylsilylimidazole, etc.) are used. In some cases (especially in quantitative analysis by GC-MS), it is useful to replace trimethylsilyl by *t*-butyldimethylsilyl group due to the easy formation of the abundant ( $M - 57$ )<sup>+</sup> peak.

Another important derivatization method of hydroxy compounds is their acylation with anhydrides of acetic, trifluoroacetic, heptafluorobutyric, etc. The latter enable very sensitive quantification to be performed using the electron-capture detector.

**Derivatization of amines** Any of the above described silylation and acylation reactions can be adopted for the derivatization of primary and secondary amines in the form of their *N*-silyl and *N*-acyl derivatives.

**Derivatization of carboxylic acids** Although the carboxyl group can also be transformed to the silyl

(ester) derivative, due to their hydrolytic instability the most widely used derivatization method here is the formation of methyl esters with methanol/hydrochloric acid at elevated temperature or with diazomethane. Double derivatization is often necessary, e.g., esterification of the carboxyl group and acylation of the amino group of amino acid and esterification of the carboxyl group and silylation of the hydroxy group(s) of bile acids.

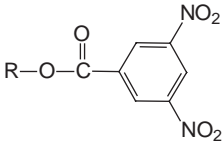

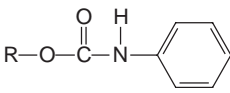

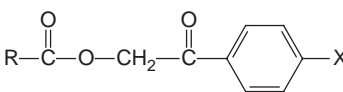

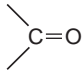

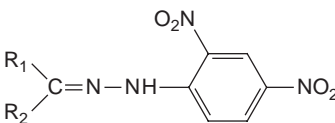

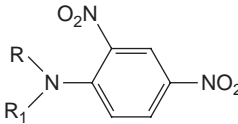

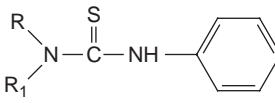

**Derivatization of inorganic materials** Various anions can be separated by GC after derivatization with, for example, pentafluorobenzyl *p*-toluenesulfonate. A variety of metals can be made volatile for GC separation by means of fluorinated  $\beta$ -diketones as the chelating agents.

### High-Performance Liquid Chromatography and LC-MS

**UV-vis derivatization** The main advantage of HPLC (introduced at the end of the 1960s) was claimed to be its much wider application field than that of GC: there are no limitations due to thermal instability, low volatility, high molecular weight, and very high polarity. This is why derivatization is much less important in HPLC than in GC. In spite of this, derivatization in HPLC is as old as the technique itself. The reason for this is that due to the low UV activity of several organic compounds the sensitivity of detection obtainable with the generally used UV detector is often not sufficient. Several reagents for the pre- or postcolumn derivatization of analytes to colored or highly UV-active derivatives have been described. Some of these are summarized in Table 1.

**Fluorimetric derivatization** Much more important is fluorimetric derivatization. The reason for this is that in biomedical analysis many of the native compounds, drugs, and drug metabolites are present at very low concentration (pg to ng ml<sup>-1</sup>) excluding the possibility of using the insensitive UV detector both for underivatized and derivatized analytes. The high sensitivity of fluorimetric detection enables the limit of detection to be decreased by several orders of magnitude. It should be noted, however, that for complex matrices as, for instance, dealt with in environmental samples the chemistry as such becomes the crucial step: the derivatization has to be successful for very low analyte concentrations in the presence of many possible matrix interferences. Nonetheless, HPLC with a fluorimetric detector is a very useful tool in biomedical analysis. Since only a limited number of analytes possess sufficiently strong native

**Table 1** Some derivatization reactions for HPLC/UV detection

		R <sub>1</sub> = H, alkyl

fluorescence, derivatization with strongly fluorescent reagents is very important. Some characteristic examples are shown in **Table 2**. It has to be noted that the number of commercially available reagents of this type is over 100.

Laser-induced fluorescence detectors enable especially sensitive determinations to be carried out. In addition to the above-mentioned classical derivatizations, diode lasers with emission in the red or near-infrared (>630 nm) require special derivatizing agents (reactive dicarbocyanine-type dyes) for carboxylic acids, amines, and thiols.

**Chemiluminescence derivatization** Derivatization enables chromatographically separated organic compounds to be determined by a selective and sensitive chemiluminescence detector. The use of isoluminol as a chemiluminescence label is an

interesting combination of pre- and postcolumn derivatization. After the HPLC separation of the derivatives of various amines and carboxylic acids with *N*-(4-aminobutyl)-*N*-ethylisoluminol, the separated components are reacted in a postchromatographic reactor with hydrogen peroxide and hexacyanoferrate in alkaline solution to obtain the chemiluminescence. Lucigenin and peroxyoxalate systems have also been used for the analysis of amino acids, steroids, etc.

**MS derivatization** As a consequence of its extremely high specificity and sensitivity, HPLC combined with MS(MS) detection is the most widely used technique in all cases when the requirement is the detection, identification, and quantitation of minor organic components in complex matrices (biomedical,

environmental, food analyses). Although in the majority of cases no derivatization is necessary to obtain the desired selectivity and sensitivity, in many cases the ionization efficiency of some analytes in soft ionization MS is not sufficient, leading to poor sensitivity. The solution to the problem is derivatization introducing permanently charged or easily ionizable moieties for electrospray ionization MS as well as proton-affinitive and electron-affinitive groups for the positive and negative atmospheric pressure chemical ionization MS, respectively. Examples are derivatization of alcohols with 2-fluoro-1-methylpyridinium, *p*-toluenesulphonate, or ferrocenoyl azide and ketones with 2-nitro-4-trifluoromethylphenylhydrazine or Girard T or P reagents (carboxymethyltrimethylammonium chloride hydrazide and carboxymethylpyridinium chloride hydrazide). The reaction scheme of the reaction of a ketosteroid is depicted in Scheme 2.

**Electrochemical derivatization** The high sensitivity attainable in HPLC with the aid of electrochemical (usually amperometric) detectors prompted the transformation of nonelectroactive analytes into electroactive derivatives. Some of the reagents or

reagent types described for the electrochemical pre- or postcolumn derivatization have already been mentioned in the previous sections dealing with other HPLC derivatization methods. For example, the isoindole derivatives obtained when primary amines or amino acids are derivatized with the *o*-phthaldialdehyde + thiol reagent are active in the oxidative mode. The same applies to the thiocarbamide derivatives of amines (reagents: isothiocyanates) and the derivatives of alcohols and amines with various reagents containing the ferrocene moiety.

The most frequently used derivatizing agents introducing electroreducible groups contain aromatic nitro moiety. Examples are 2,4,6-trinitrobenzenesulfonic acid, 1-fluoro-2,4-dinitrobenzene, and 3,6-dinitrophthalic anhydride for the derivatization of amines, 4-nitro- or 2,4-dinitrophenylhydrazine reagents for aldehydes and ketones, 4-nitrobenzyl bromide and 4-nitrophenacyl bromide for carboxyl groups, etc.

### Supercritical Fluid Chromatography

The importance of supercritical fluid chromatography (SFC) is not comparable with that of the previously discussed chromatographic methods. The aim of

derivatization here is either to increase the solubility of highly polar analytes (e.g., carbohydrates) in CO<sub>2</sub> by permethylation, persilylation, peracetylation, or to improve the selectivity and mainly the detection limit using various detectors making use of the derivatization strategies described in the sections dealing with GC and HPLC.

### Capillary Electrophoresis and Related Techniques

Derivatization is often used in CE either to introduce electric charge to the uncharged analyte molecule or to improve the sensitivity of its detection and quantitation.

**Introduction of electric charge to the analyte molecule** In the course of the electrophoretic procedure, only electrically charged molecules migrate separately, toward the cathode or the anode; uncharged molecules move together toward the cathode driven by the electroosmotic flow. These molecules can be separated in the CE instrument by the application of micellar electrokinetic chromatography (MEKC). Another method (much less widely used but still remarkable) is to introduce electric charge to the molecule by means of suitable derivatization reactions prior to the CE run. Examples are reductive amination of carbohydrates using 2-aminopyridine as the reagent, which leads to charged molecules in acidic medium and the derivatization of ketosteroids with Girard P and T reagents (already mentioned in section “MS derivatization”). **Figure 1** shows the electropherogram of ethisterone and its synthetic precursors after derivatization with Girard T reagent. The two-step reaction of the intermediate diketo steroid androstenedione is shown in **Scheme 2**.

**Improving sensitivity** While the above discussed aspect of derivatization in CE aiming at introducing electric charge to the uncharged analytes is only seldom used, the other aspect, namely the improvement of the sensitivity by introducing chromophores and fluorophores, is of great importance. What is described about the potential of pre- or postcolumn derivatization in the section ‘High-performance liquid chromatography and LC–MS’ is also applicable to CE and related techniques (capillary electrochromatography (CEC) and MEKC): the same or similar derivatization reactions can be used. The result is extremely high sensitivity, enabling even the most delicate bioanalytical methods to be solved especially if the laser-induced fluorimetric detection with argon ion or helium–cadmium lasers is used. For example, as low a limit of detection as  $10^{-18}$  mol per injection was measured after the derivatization of peptides

**Figure 1** CE separation of ethisterone (17 $\alpha$ -ethynyl-17-hydroxy-androst-4-ene-3-one) and its synthetic precursors after derivatization with Girard T reagent. Key: 1, Girard T reagent; 2, androst-4-ene-3,17-dione-bis-Girard T derivative; 3, androst-4-ene-3,17-dione-3(mono)-Girard T derivative; 4, 3 $\beta$ -hydroxy-androst-5-ene-17-one Girard T derivative; 5, ethisterone Girard derivative. pH 4.8; voltage, 25 kV; temperature, 15°C; injection time, 3 s; UV detector: 250 nm. (Reprinted with permission from Görög S, Gazdag M, and Kemenes-Bakos P (1996). *Journal of Pharmaceutical and Biomedical Analysis* 14: 1115–1124; © Elsevier.)

with suitable dye reagents such as tetramethylrodamine 5-isocyanate isomer G.

### Immunoanalytical Methods

Immunoanalytical methods occupy an important position in bioanalytical chemistry. Chemical derivatization plays a fundamental role in this technique. Small analyte molecules (haptens) are covalently bound to proteins to raise the antibody, which is the basis for their highly selective and sensitive assay. Various labeled derivatives of the analyte are then prepared for competitive binding on the antibody (radiolabeling, labeling for enzyme immunoassay, fluorescence immunoassay, fluorescence polarization immunoassay, and luminescence immunoassay). These derivatization reactions are carried out by the

manufacturers of the various commercially available kits rather than the analysts themselves. However, in the case of enzyme immunoassays the basis for the measurement is usually chemical reactions, the products of which are measured spectrophotometrically or fluorimetrically. Two examples of the great variety of reactions used in the various assay methods are the reaction between hydrogen peroxide and 2-phenylenediamine catalyzed by peroxidase enzyme leading to a quinonediimine chromophore. If the reaction partner of hydrogen peroxide in this reaction is phenylacetic acid and the reaction product is further reacted with glycine, a fluorophore is formed enabling much higher selectivity and sensitivity to be attained especially if time-resolved fluorimetry (briefly introduced in the section 'Fluorimetry') is adopted.

## Chiral Derivatization

The simultaneous determination of enantiomers of drugs and other materials of biological importance and the estimation of enantiomeric purity of drugs administered as pure enantiomers are among the most important tasks in contemporary bioanalytical chemistry. Although a great variety of chiral stationary phases are commercially available for the direct separation of enantiomers by GC, TLC, SFC, and especially by HPLC, the classical approach, i.e., transformation of the enantiomers to a pair of diastereomers by derivatization with homochiral reagents followed by their separation using achiral chromatography or CE, is still a widely used general method. Two general methods are available for the formation of the diastereomers: formation of covalently bound derivatives with homochiral derivatizing agent prior to the chromatography and incorporation of the homochiral agent into the mobile phase to form a pair of diastereomeric adducts.

### Formation of Covalently Bound Diastereomeric Derivatives

In addition to the general requirements toward derivatization reagents and reactions it is important that the enantiomeric purity of the reagent is high (at least 99.9% if the aim of the analysis is the enantiomeric purity check of chiral drugs). The reagent should be enantiomerically stable (racemization must not occur), and kinetic resolution during the chromatographic run should be absent. An important advantage of this approach is that in possession of both enantiomers of the homochiral reagent, the elution order can be adjusted in such a way that the enantiomeric impurity is eluted first, thus enabling lower detection and quantitation limits to be obtained (see Figure 2).

Although the first separations after enantiomeric derivatization described in the literature were gas chromatographic procedures, at present only HPLC methods are widely used. Of course, in this case only precolumn derivatization is applicable. For the derivatization of the amino group the following main types of chiral derivatizing agents are used (the type of the reaction product in parentheses): acyl chlorides and anhydrides (carboxamides), chloroformates (carbamates), isocyanates (carbamide derivatives), isothiocyanates (thiocarbamide derivatives), acylamino-haloaryl derivatives (acylamino-amino-aryl derivatives), *o*-phthalaldehyde + chiral thiol (isoindoles). The effect of the choice of the derivatizing agent (d or l) is demonstrated in Figure 2, where the amino acids in a sample of plant origin were derivatized with *o*-phthalaldehyde + d- and l-N-isobutyrylcysteine, respectively.

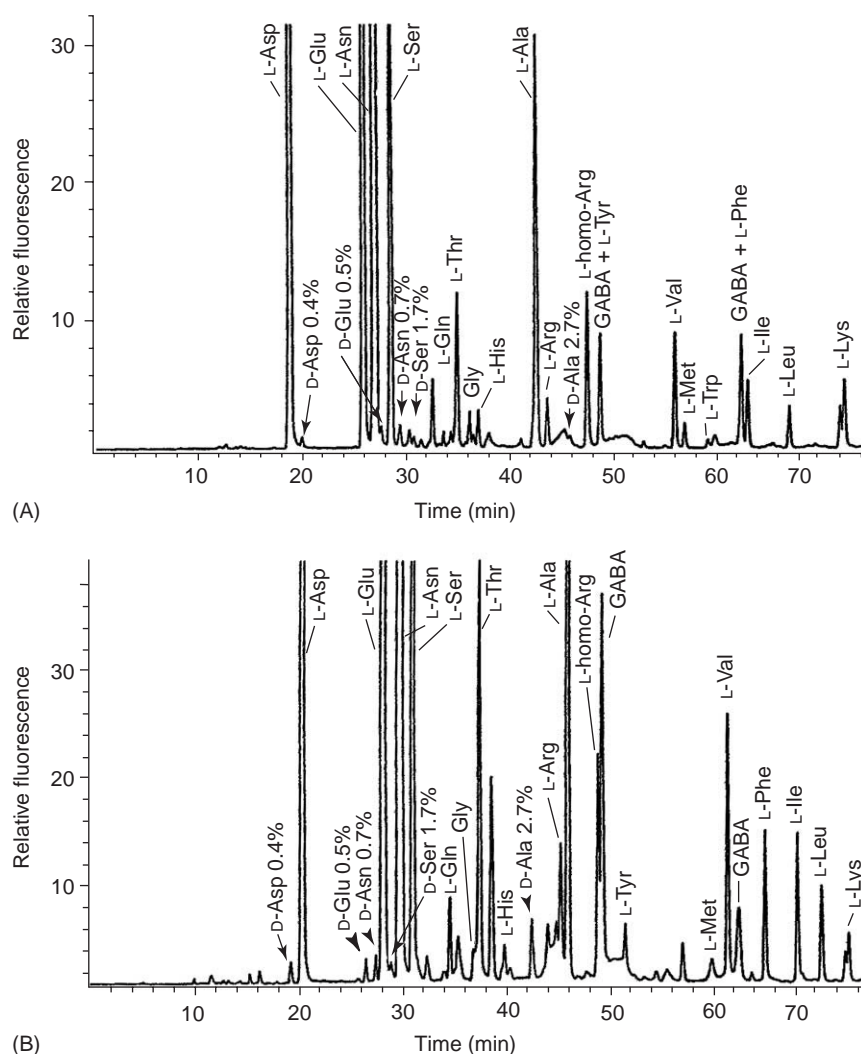

The main chiral derivatizing agents for alcohols and phenols are acyl chlorides and anhydrides (esters), isocyanates (urethanes), acyl nitriles (esters), while for carboxylic acids the most generally used derivatizing agents are chiral amines that can be applied after the activation of the carboxylic group in different ways.

### Formation of Diastereomeric Adducts

Enantiomeric separation based on dynamic formation of a pair of diastereomeric adducts (inclusion complexes, ion-pairs, chelates) is also a widely used method. In this case (mainly in HPLC but with an increasing rate also in CE, CEC, MEKC), the homochiral reagent is dissolved in the mobile phase and the main factor creating the basis for the separation of the enantiomers is the difference between the stability constants of the two diastereomers. The most frequently used homochiral reagents are cyclodextrins and their derivatives, but several applications have been described with chiral ion-pair forming agents such as 10-camphorsulfonic acid and quinine, chiral chelates of copper(II), which serve as the basis of ligand-exchange chromatography.

## General Aspects: Types of and Requirements toward Derivatization Reactions and Reagents

As for the timing and arrangement of derivatization reactions in the case of (mainly spectroscopic and spectrophotometric/fluorimetric) methods not involving chromatographic or electrophoretic separation steps, the question is whether the reaction is run online (automatic analyzers with segmented or non-segmented flow) or offline prior to the measurement.

**Figure 2** HPLC elution profile of L and D-amino acids from freshly prepared apple juice (Golden Delicious) derivatized as the isoindoles with (A) *o*-phthalaldehyde-*N*-isobutyl-L-cysteine; (B) *o*-phthalaldehyde-*N*-isobutyl-D-cysteine; Column: Hypersil ODS (250 × 4 mm; 5 μm; mobile phase, gradient elution; (A) = 23 mmol l<sup>-1</sup> sodium acetate (pH 5.95); (B) methanol-acetonitrile (600:50 v/v), linear gradient from 0% B to 53.5% B in 75 min; flow rate: 1 ml min<sup>-1</sup>; fluorescence detection (230 nm excitation, 445 nm emission). (Reprinted with permission from Brückner H, Haasmann S, Langer M, Westhauser T, and Wittner R (1994). *Journal of Chromatography A* 666: 259–273; © Elsevier.)

In the case of chromatographic or electrophoretic methods the derivatization reaction can take place before the separation (precolumn derivatizations) or between the column/capillary and the detector (postcolumn derivatizations). The arrangement of pre-column derivatizations can be offline (reaction separated from the chromatographic/electrophoretic procedure in time and space) or online (precolumn reactor before the injector). In the case of postcolumn derivatization, only online arrangement can exist: the reactor should be inserted between the column/capillary and the detector. The derivatization in the reactors takes place usually in the solution phase, but solid-phase reactors where the reagent is immobilized on the surface of a solid support

have also gained importance. An important application of postcolumn derivatization is in amino acid analyzers where amino acids are first separated by (usually ion-exchange) chromatography followed by transformation in a postcolumn reactor to colored derivatives with ninhydrin or fluorescent derivatives with an *o*-phthalaldehyde-thiol reagent for the spectrophotometric or fluorimetric measurement.

The requirements toward the derivatization reagent and reaction depend on the analytical problem to be solved. Generally, it is advantageous if the reaction conditions are as simple as possible. Side-reaction-free and rapid one-pot reactions, reaching completion within a few minutes at room temperature, are suitable for automation as ideal cases. Of course,

compromise can be made in many cases. For example, it is not an obstacle if heating is necessary to the completion of the reaction; moreover, 100% yield of the reaction is not by all means necessary (the yield should be, however, reproducible under the specified reaction conditions). The necessity of an extraction step is tolerable; moreover, this can also be automated.

The application of dual-purpose reagents is very advantageous. For example, of the derivatizing agents discussed in the preceding sections Girard T reagent is a useful tool to introduce electric charge to uncharged molecules, thus enabling their CE analysis to be performed; but at the same time it greatly improves the UV detectability of spectrophotometrically poorly active ketones. Moreover, it also improves the sensitivity of HPLC–MS detection. In the case of separation of spectrophotometrically poorly active enantiomers, it is advantageous if the homochiral derivatizing reagent transforms the analyte to spectrophotometrically or fluorimetrically active diastereomeric derivatives. Most of the reagent types shortly summarized in the section ‘Chiral derivatization’ to fulfill this requirement (see Figure 2).

### Introduction

'Dioxins' is a generic term for the polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs), comprising 75 and 135 congeners, respectively. The generalized structures for these two groups of molecules are shown in Figure 1. The term dioxin is also used to refer specifically to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), the most toxic congener. In addition to the chlorinated dioxins, brominated analogs of PCDDs and PCDFs can also be formed when organic material containing bromides is incinerated. Throughout this article the term dioxins is used to refer to the family of chlorinated dioxins and furans, although the analytical principles described are generally applicable to the brominated congeners as well.

Dioxins occur as unintended by-products of incomplete combustion and certain chemical processes. The International Agency for Research

on Cancer and the United States Environmental Protection Agency (USEPA) have classified TCDD as a known human carcinogen. In view of the widespread distribution of dioxins in the environment, these compounds are being monitored routinely in air, water, soil, sediments, biota, and food-stuffs. Regulatory agencies have identified dioxins as priority environmental pollutants for routine monitoring, with the aim of reducing both emissions and exposures.

### Analytical Purpose and Requirements

The need for analysis of PCDDs and PCDFs arises from the apparent high toxicity of TCDD and 16 other 2,3,7,8-substituted congeners. This toxicity has been established from numerous studies on laboratory test animals. The true magnitude of their toxicity to humans probably cannot be defined, but precautionary guidelines for dietary intake limits have nonetheless been set in the low picogram per kilogram of body weight per day range (e.g., tolerable daily intake in the UK is 2 picogram per kilogram of body weight per day).

In general, the analysis of PCDDs and PCDFs is intended to determine their sources and pathways of human and wildlife exposures, and their environmental fates. The environmental levels and toxicological data are also used for risk assessment purposes. Several countries have promulgated compliance monitoring of wastes, in order to regulate the release of dioxins into the environment. In all cases, the analytical procedures used must be capable of measuring background environmental concentrations ranging from ng per g for soils and sewage sludge to fg l<sup>-1</sup> and fgm<sup>-3</sup> in water and air, respectively.

**Figure 1** Generalized structures of PCDDs and PCDFs.

Regulatory monitoring of emissions from industrial processes requires reliable determination of sub-nanogram per cubic meter in stack gases and a few parts per quadrillion ( $\text{pg l}^{-1}$ ) in water. From these examples, it is clear that a distinctive feature of analysis of PCDD/Fs is the need to achieve rather low detection limits – typically a few picograms in the samples analyzed in order to monitor and control the discharge of these compounds. PCDDs and PCDFs occur in environmental and biological matrices as complex mixtures with various other contaminants, such as polychlorinated biphenyls (PCBs) and biogenic compounds (lipids, proteins). Analyses of dioxins at picogram or femtogram levels are complicated by the presence of myriad of interfering compounds. Accurate determination of trace levels of dioxins in complex environmental matrices is a demanding analytical task involving extensive sample treatment and rigorous quality control during the instrumental analysis.

Another critical issue in the analysis of dioxins is the specificity at the individual congener level for use in risk assessments. As noted earlier, the congener with the highest toxicity is 2,3,7,8-TCDD. Other congeners whose substitution includes the same symmetrical arrangement of chlorines also exhibit high toxicities. There are a total of 17 such PCDD and PCDF congeners, whose relative toxic potencies vary over as much as four orders of magnitude. In order to express the toxic potential of a complex mixture of individual congeners as a single integrated parameter, the concept of the toxic equivalency (TEQ) value was developed. This requires the specific determination of the most toxic congeners (2,3,7,8-substituted), normalization of each of them to a 2,3,7,8-TCDD equivalent using a set of factors (called TCDD equivalency factors, or TEFs) that reflect their relative toxicities, and then summation. The most commonly used TEFs are those that were proposed by the World Health Organization in 1998. TEQs are a useful means of expressing toxicity in regulatory issues and risk assessment problems. Several legislative guidelines for PCDDs and PCDFs are based on TEQs rather than on concentrations of individual or all congeners. The legislative usage necessitates the determination of concentrations of individual congeners rather than total dioxins.

Considerable advances have been made in the analytical techniques used to measure dioxins over the last three decades. They range from rapid biological screening techniques, utilizing *in vitro* gene expression cell bioassays and immunoassays (referred to as bioanalytical techniques), to comprehensive two-dimensional gas chromatographic ( $\text{GC} \times \text{GC}$ ) separation and identification by time-of-flight mass

spectrometer (TOFMS). Dioxin analyses performed with combined high-resolution capillary GC/high-resolution MS (HRGC–HRMS) are still the method of choice, although time consuming and relatively expensive. While HRMS methods are continually becoming faster and less expensive, as the use of automated extraction and cleanup procedures increases, bioanalytical methods also offer advantages in speed, expense, and field portability. The bioanalytical methods can be used for the rapid and inexpensive detection and relative quantification of TEQs. Details regarding the use of cell bioassays and immunoassays for the detection of dioxins have been reviewed elsewhere. Quick, cost-effective field screening and monitoring techniques, such as the bioanalytical methods coupled with conventional HRMS testing, can increase the amount of information that is available for the determination of the presence and concentration of contaminants that could impact the environment and human health.

Compliance environmental monitoring of PCDDs and PCDFs requires the analysis of the 17 2,3,7,8-substituted congeners. Although non-2,3,7,8-substituted congeners are found in the environment, they are not monitored routinely, due to their low bioaccumulation potential and toxicity. However, analysis of non-2,3,7,8-substituted congeners can be useful in tracing the sources and fates of dioxins in the environment.

Current standard methods of dioxin analysis using HRGC–HRMS require rigorous quality assurance and quality control. The samples undergo extensive treatment and extraction prior to instrumental analysis. Each step in the sample handling process is critical in order to discriminate possible interferences from other substances that may be present and to avoid analyte losses; thus, the final qualitative and quantitative measurements can be made with the greatest possible precision and accuracy, according to the requirements of the method. The analytical process includes representative sampling, careful handling of samples, extraction, cleanup, GC separation, detection, and accurate quantification. The cleanup steps provide a suitable removal of the bulk matrix and some interfering compounds; HRGC allows appropriate separations among the various congeners; and HRMS affords a sensitive and selective method of detection. Finally, an isotopic dilution technique based on the use of  $^{13}\text{C}$ -labeled standards provides the reliable quantification needed to quantify the dioxins present.

The basic requirements that must be met by an analytical procedure for dioxin measurement are: high sensitivity, selectivity, and specificity, and high

accuracy and precision. In general, sample extraction, cleanup, chromatographic separation, and mass spectral identification and quantification methods together form a delicately matched set, each element of which is designed to meet the basic requirements.

## Sample Collection and Preparation

The quality and utility of the analytical data depend on the validity of the sample and the adequacy of the sampling program. The number of individual samples that need to be analyzed will depend on the kind of information required by the investigation. The collection of samples for dioxin analysis requires the application of standard practices, to ensure that representative samples are obtained that contain sufficient analyte to allow effective analysis. All of the equipment and containers used to collect and store samples should be precleaned with organic solvents, typically acetone and hexane, to reduce interferences and to ensure that they are free of dioxin contamination. They may additionally be heated in a muffle furnace at  $\sim 450^{\circ}\text{C}$  for 2 h if they are made of borosilicate glass. Samples are kept on ice or at  $< 4^{\circ}\text{C}$  from the time of collection until receipt at the analytical laboratory. Samples must be frozen upon receipt at the laboratory and maintained in the dark at  $< -10^{\circ}\text{C}$  until prepared for analysis. In the analysis of dioxins, there is no maximum holding time, as dioxins are stable and not subject to loss or degradation, when handled in accordance with standard operating procedures. Some regulatory agencies recommend a sample holding time of 7 days for aqueous samples and for up to 1 year for solid matrices, and an extract holding time of 40 days for water samples to up to 1 year for other matrices. Samples with high moisture content (e.g., vegetables) may dehydrate unless extracted immediately after collection. Freezing at  $< -10^{\circ}\text{C}$  may dehydrate such samples. Adequate precautions should be taken to account for the loss in moisture content while storing the samples in a freezer.

There are unique problems associated with the sampling of gaseous and aqueous matrices. Because of the low concentrations of dioxins in these media, high-volume sampling devices are used to collect several tens to hundreds of liters of water, or several hundreds to thousands of cubic meters of air. The sampling of dioxins in gases is complex and beyond the scope of this article, but it utilizes a variety of solid and liquid traps, tetrafluoroethane filters, resin beds, polyurethane foam plugs, reagent traps, and adsorbents in series, to collect both particulate and vapor-phase PCDDs and PCDFs. Aqueous samples

are preconcentrated on a glass fiber filter combined with absorbing resin cartridges. It is essential that these sampling media are precleaned with organic solvents and spiked with the appropriately labeled analogs, at the beginning of the sampling train. For biological fluids such as milk, urine, and blood, it is essential that an appropriate set of isotopically labeled analogs of the target congeners are introduced into the sample through spiking prior to processing or pretreatment.

Sample mass or volume has a profound influence on the detection limits for dioxins. For biological fluids such as blood plasma, the conventional HRGC–HRMS method requires a sample volume of 40–60 ml to attain a detection limit of  $\leq 1$  pg per g. Collection of 40–60 ml blood is laborious and problematic, particularly from infants and aged persons. Unless other methods such as solvent-cut, large-volume injection systems are used, the nominal sample size of 5–10 ml is not adequate to measure sub-pg per g levels of dioxin in blood.

Legislation has required the detection of dioxins in food and feed at fg per g (parts per quadrillion) levels. One way in which to achieve this detection level is by increasing the mass of the samples extracted. Nevertheless, it should be noted that the extraction of a large amount of sample can also increase the amounts of impurities and interference, which are coextracted, requiring additional cleanup steps. Optimization of the mass of samples used for extraction is necessary to determine which cleanup steps need to be used, and to attain the required level of detection.

The content of moisture or lipid in biological samples, and of organic carbon in soil or sludge, can account for variations in dioxin concentrations measured between samples. Therefore, normalization of concentrations on dry and/or lipid weight or organic carbon would improve the comparability of concentrations across samples.

Sample pretreatment involves modification of the physical form of the sample in such a way that the dioxins can be extracted efficiently. Some environmental matrices such as fly ash require pretreatment involving acid attack, usually with HCl, to destroy the structure of the matrix and to allow better recovery of the dioxins. For certain samples, denaturants are added so as to destroy any protein–analyte interactions and disrupt micellar formation, both of which can decrease recoveries of dioxins. For example, formic acid has been used as a denaturant prior to extraction of dioxins in plasma or serum. Sodium or potassium oxalate (20 mg per g milk) is added to milk samples to disrupt fat globules. Depending on the type of sample, grinding, homogenization, and blending of various sample phases

may be needed. For solid matrices, moisture in samples should be removed either by freeze-drying or by grinding with anhydrous sodium sulfate, when the sample is extracted with nonpolar organic solvents.

## Extraction

In general, extraction methods are standardized around liquid–solid extraction (e.g., Soxhlet), solid-phase extraction (SPE), and liquid–liquid extraction (LLE). The choice of procedures is dependent upon the amount and type of sample requiring extraction and the types of other compounds that may be present. Extraction techniques for food and other biological matrices are generally based on the lipophilic properties of dioxins, and therefore the extraction methods are based on the extraction of lipids from the sample matrix. Methods for the isolation of lipid fractions in food samples such as butter, oil, and animal fats involve direct dissolution with *n*-hexane or light petroleum to the desired fat concentration. Soxhlet extraction with, for example, toluene is the most common liquid–solid extraction procedure applied to solids. Although this technique achieves good extraction rates, it requires a long extraction time (24–48 h) and large volumes of solvent (300–400 ml). After extraction, the solvent must be concentrated, which results in air emissions or costly solvent disposal.

Saponification under alkaline conditions (in the presence of ethanolic KOH), followed by extraction with organic solvent is often employed for the analysis of large amounts of fats (several 10 s to 100 s of g). However, this method is known to degrade the more highly chlorinated dioxins, particularly octachlorodibenzofuran, thus leading to artifacts.

Over the past few years, efforts have been made to develop alternative extraction techniques that allow more efficient extraction, along with reduced solvent volumes, in shorter times, and incorporating high levels of automation. Methods such as accelerated solvent extraction (ASE) uses conventional liquid solvents at elevated pressures (1500–2000 psi) and temperatures (50–200°C) to extract solid samples rapidly, with much less solvent than is required by Soxhlet methods. The sample is placed in extraction cells, which are filled with an extraction solvent and heated for 5–10 min, with the expanding solvent vented to a collection vial. The entire procedure is completed within 10–20 min per sample, and uses only 15–20 ml of solvent. Similarly, microwave-assisted solvent extraction (MAE) requires a relatively short extraction time (<1 h) and small amount of solvent (~30 ml), and thus offers an attractive

alternative to the Soxhlet procedure. MAE uses microwave radiation that enables instantaneous and efficient heating in the presence of microwave-absorbing compounds. However, this technique requires further filtration to obtain the final extract. Both ASE and MAE require a relatively high initial investment. Supercritical fluid extraction (SFE) of solids offers a means of exercising close control over extraction conditions, and thus potentially improved repeatability. Carbon dioxide is most often used as the extraction solvent, because of its moderate critical temperature (31°C) and pressure (1070 psi). However, optimum SFE conditions vary from one sample matrix to another. Because of their advantages in speed, cost, and solvent quantities, ASE, MAE, and SFE are promising alternatives to the conventional Soxhlet extraction method.

High-capacity absorbent phases are used for the extraction of dioxins in aqueous samples. These phases trap the target molecules, which can be recovered later by reverse elution with a suitable solvent such as dichloromethane, hexane, or ethanol. SPE of dioxins, using a variety of commercially available sorbents, has been used for various biological fluids such as serum. LLE is used to extract lipid-phase containing dioxins from aqueous samples such as milk. LLE of milk involves mixing with sodium oxalate and ethanol or methanol, followed by repeated extractions using a combination of organic solvents such as acetone–pentane or diethyl ether–light petroleum. Solid-phase microextraction (SPME), which utilizes various coated adsorbents and/or absorbents on a fiber contained in a syringe-like device, has been tested for its utility in dioxin analysis of aqueous media. This method is based on selective absorption of dioxins to carbon SPME fibers and is being further validated to establish its applicability.

Because it is not possible to achieve complete extraction in all cases, all of the time, it is necessary to test the effects of varied extraction conditions (such as Soxhlet cycles, duration, solvent volume, and sample weight) and then establish a rigorous regimen by which optimum performance can be maintained. It should be noted that the addition and recovery of isotopically labeled analogs does not provide a reliable check on extraction efficiency, since the form of these analogs is different from that of the native analytes within the sample matrix. Inclusion of a quality check sample or standard reference material in each batch of samples analyzed does allow extraction performances to be monitored and controlled, to ensure reproducibility.

## Extract Purification

The isolation of dioxins as a group is aided by these compounds' resistance to oxidative and hydrolytic destruction. Thus, contact with strong acid and/or base can be used to eliminate much of the co-extracted material. Direct contact of concentrated extract with sulfuric acid is used to remove lipids, proteins, and certain oxidizable materials in the extracts. Gel permeation chromatography (GPC) has also been used to remove high molecular weight interferences including lipids. GPC presents several advantages, including robustness, versatility, and an ability to be used repetitively without the need for regeneration. Fat retainers and lipophilic gels have also been used to extract or cleanup lipids from sample matrices. The adsorbent columns do not allow the handling of more than 1 g of lipids, in order that they are able to produce clean extracts. Therefore, analyses of foods of animal origin, especially dairy products, require additional fat-removal steps. A multistep purification procedure is routinely followed to concentrate the final extract to appropriate volumes of solvent, thus allowing the detection of analytes at the ultratrace levels at which they usually occur. Successive cleanup steps using chromatographic adsorbents (silica, Florisil, alumina, and activated carbon) are most commonly used for cleanup and fractionation of dioxins from other interferences. Polypropylene tubes filled with sorbents are commercially available (as SPE cartridges). A recent technique, referred as multilayer silica gel column chromatography, involves the passage of concentrated extract through a column containing separate layers of acid- and base-modified silica, sandwiched between layers of nonmodified silica. Dioxin isomers pass through the column unaffected, while the layers retain polar contaminants and other extractables that can act as interferents during the GC analysis. The column can be connected to a vacuum manifold, to facilitate the extraction process and to decrease extraction time. Concentration of the eluate from such a column yields a solution containing not only PCDDs and PCDFs, but also other compounds such as PCBs, polychlorinated naphthalenes (PCNs), and polybrominated diphenyl ethers, all of which are similarly resistant to acid and/or base attack. The latter types of compounds are separated from the dioxins through a combination of liquid chromatography with a carbon column (porous graphitic carbon or pyrenyl ethyldimethyl silylated silica), making use of the relatively small differences between the polarities and sorptive characteristics of the dioxins and those of the PCBs and other chemically similar groups of molecules. Alumina, Florisil,

and/or activated carbon are adsorbents commonly used to separate PCBs from dioxins. A major drawback of carbon as a packing material is its high back-pressure. Therefore, activated carbon dispersed on a glass fiber, polyurethane foam, or silica gel support, or more recently on C<sub>18</sub> packing, is also used. This technique separates dioxins from PCB congeners based on  $\pi$ -cloud interaction with the graphitic carbon surface. Dioxins, with their rigid planar structures, are separated from PCBs because they are more strongly adsorbed onto the carbon than are the PCBs. However, PCNs and other planar compounds also co-elute with dioxins. Success at this stage depends on precise control over materials preparation and elution procedures, as well as on the choice of stationary and mobile phases. Hexane or a combination of hexane and dichloromethane is used frequently as the mobile phase. More complex mobile-phase profiles are required to separate dioxins from coplanar PCBs and PCNs, because of their similar adsorptive properties. These methods are time consuming and require manual sample preparation that may give rise to a decrease in precision and accuracy, in addition to the risks of human exposure. Lot-to-lot variations of adsorbents and solvents can lead to irreproducibility in the elution profiles of dioxins.

The development of extract purification techniques is directed, on the one hand, toward automation, and, on the other hand, toward the development of more selective adsorbents such as immunosorbents. Recently, automated cleanup systems have been developed based on the use of pressurized column chromatographic procedures. This is regarded as an alternative system that bypasses most of the disadvantages of the conventional cleanup methods, given its capacity for processing automatically different samples simultaneously in  $\sim 1$  h. An automated cleanup system that uses a classical set of multilayer silica, basic alumina, and carbon columns has been developed to increase the number of samples that can be treated simultaneously. Several modifications and upgrades of this system are currently examined for the analysis of dioxins in both abiotic and biotic samples. Immunoaffinity chromatography (IAC) has been investigated as a means to simplify cleanup of extracts. IAC columns are generated from antidioxin antibodies and are shown to bind dioxins selectively from samples. The IAC procedure is relatively fast and uses fewer organic solvents than conventional methods. However, it is not compatible with high-fat matrices and is not fully selective for all of the 17 toxic PCDD/F congeners.

Recoveries of dioxins through adsorbent columns must be checked and validated by spiking with known concentrations. Particular adsorbency

characteristics (size, weight, conditioning, etc.) and solvent polarity, elution rate, volume, and elution profiles need to be optimized to separate dioxins from other interferences. While the use of stable-isotope dilution calibration allows recovery losses to be corrected for, in calculation over an established range, actual recoveries should be monitored to ensure that procedures are under control.

## Chromatographic Separation

The GC separation of all target congeners is critical to the successful analysis of dioxins. The development of capillary GC columns has permitted congener-specific determination of a number of these mixtures. In principle, polar or nonpolar capillary columns (normally combined with splitless or on-column injection) may be used. The isomer-specific elution patterns of dioxins are well established for such widely used column coatings as 5% diphenyl-95% dimethyl-polysiloxane, 14% cyanopropylphenyl-86% methyl polysiloxane, and 90% biscyanopropyl-10% cyanopropylphenyl polysiloxane. However, chromatographic separation of the toxic isomers from all of the nontoxic isomers requires the use of at least two columns with differing compositions and polarities. To enhance the resolution, longer or narrower bore columns, or a combination of both, have been used. Nevertheless, several critical congeners co-elute with others. Through the use of nonpolar columns, a separation can be achieved between homolog groups. In addition, nonpolar columns separate the 2,3,7,8-substituted congeners from one another; however, they fail to resolve this group of congeners from the nontoxic congeners. With polar columns, the resolving power improves, but incomplete separation still remains for 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and 1,2,3,4,7,8-HxCDF (Table 1). TCDF is the most difficult to resolve and requires medium polar columns. Nonpolar columns

are frequently used for the analysis of biological samples, as these samples generally do not contain congeners other than the 2,3,7,8-substituted ones. Polar columns are required for isomer-specific analyses of PCDDs and PCDFs in samples that may contain nonlaterally substituted isomers, such as environmental samples, fly ash, ambient air, and PCDD/F-contaminated products of various origins. Injection onto two different columns is recommended for an unambiguous determination. Several chromatographic columns are being developed for the purpose of overcoming the need for dual-column injections.

The chief concerns with single-column GC analysis are lack of resolution, lack of unambiguous identification, and lack of robustness. Multidimensional GC (MDGC) has been used as a complementary technique to resolve difficulties in the separation of co-eluting compounds. This technique provides an alternative to use of additional sample pretreatment steps, which could lead to a further loss of analytes. One of the MDGC methods, comprehensive GC  $\times$  GC, has been shown to be very useful for the separation of complex mixtures of environmental contaminants, including dioxins. This technique employs a pair of coupled columns of differing selectivities and it subjects the entire sample to a two-dimensional separation. Effluent gas from the first column is modulated to produce sharp chemical pulses, which are rapidly separated on the second column. A separation plane is produced by the orthogonal retention-time axes for the two columns. GC  $\times$  GC offers increased sensitivity and selectivity and improved reliability in the identification of target compounds.

## Spectroscopic Detection

Mass spectrometric identification is the most commonly used method in dioxin analysis. The coupling of GC and MS has been recognized as the most practical and widely used method of measuring dioxins. Although both high- (HRMS) and low-resolution mass spectrometry (LRMS) have been used in dioxin analysis, for analyses involving multiple congeners at the parts per trillion or parts per quadrillion level, an isotope dilution technique using HRMS is essential. LRMS is useful as a screening tool, but it is not a recommended technique for stack-emission data for PCDD/Fs; instead, the LRMS method was designed for samples that contain levels of dioxins in the parts per billion range.

For certain regulatory measurements, the use of HRMS is obligatory (e.g., USEPA method 1613, European Union method EN1948-1/2/3). HRMS is operated in the EI mode (electron energy 38 eV) at a

**Table 1** Common coelutants in the GC analysis of 2,3,7,8-substituted dioxins and furans using 5% diphenyl-based microbore column chromatography

<i>Toxic congener</i>	<i>Co-eluting nontoxic congener</i>
2,3,7,8-TCDF	1,2,4,9-; 2,3,4,6-; 2,3,4,8-; 1,2,7,9-; 2,3,4,7-TCDFs
2,3,7,8-TCDD	1,2,3,9-; 1,2,3,7-/1,2,3,8-TCDDs
1,2,3,7,8-PeCDF	1,2,3,4,8- PeCDF
2,3,4,7,8-PeCDF	1,2,6,7,9-; 1,2,3,6,9-; 1,2,4,8,9-; 2,3,4,8,9-PeCDFs
1,2,3,4,7,8-HxCDF	1,2,3,4,6,7-HxCDF
2,3,4,6,7,8-HxCDF	1,2,3,6,8,9-HxCDF
1,2,3,7,8,9-HxCDD	1,2,3,4,6,7-HxCDD

resolving power of 10 000. Under these conditions, various ions (including isotopically labeled ions) are monitored in the selected ion monitoring mode. Two characteristic ions of the molecular cluster are selected for each of the congener groups, from tetra- to octa-PCDD and PCDF. An important advantage of HRMS is its capability of allowing to test for suppression by interferent compounds, via lock mass monitoring.

Tandem MS (MS/MS) has been reported to be a valuable technique for improved selectivity in analysis of PCDD/Fs. Increased selectivity is obtained by two mass selection stages and collisionally induced dissociation (CID) of characteristic ions. PCDD/F molecular ions pass through the first mass analyzer to a collision cell, where CID occurs and specific daughter ions, usually the  $[M-COCl]^+$  ions, are then selected in the second mass analyzer. Although this technique provides high selectivity, the sensitivity is relatively low compared to the HRMS technique. Other disadvantages of GC-MS/MS include high initial cost and high maintenance costs. Recently, ion-trap tandem MS (ITMS-MS) has become an interesting alternative to HRMS because of its low cost. Under optimal ionization conditions, ITMS-MS performs reproducible quantification of dioxins. ITMS-MS's detection limit of TCDD is in the range of 25–50 fg.

As chromatographic run times are shortened through the use of microbore columns, conventional MS (quadrupole and magnetic sector) are unable to scan fast enough ( $\leq 1$  s per spectrum) that they can produce sufficient data points to accurately define a chromatographic peak. TOFMS can operate at scan speeds of more than 100 spectra per second. This speed provides a number of advantages over other mass spectrometers, such as the capability to deconvolute mass chromatograms for compounds with retention times that differ by more than  $\sim 150$  ms. A combination of GC  $\times$  GC with TOFMS provides both the sensitivity and selectivity required for the analysis of dioxins in environmental samples, and its application is being investigated.

The successful identification of dioxins is dependent on the following criteria: (1) retention times of chromatographic peaks must fall within the appropriate chromatographic windows; (2) simultaneous responses for the two masses monitored must be obtained; (3) signal-to-noise ratios must be  $> 3$ ; and (4) relative isotopic peak ratios must be within  $\pm 15\%$  of the theoretical values. Once these criteria are satisfied, assignment of congeners is performed by comparing the retention times with those of the corresponding labeled compounds added as internal standards. Quantification is carried out by an

isotopic dilution technique, based on the addition of labeled standards. Relative response factors for the individual isomers are obtained using five or more calibration standard solutions containing both native and labeled congeners at the concentration range in which the sample values fall. In addition to internal standards, which are spiked at an early stage of sample extraction, injection internal standards (which are usually non-2,3,7,8  $^{13}C_{12}$  labeled analogs) are added to the cleaned extract immediately prior to GC-MS analysis and provide a means to correct for variations in injection efficiencies; thus, actual recoveries of internal standards can be calculated. The recoveries of labeled standards are calculated using a mixture of two labeled PCDDs added before the HRGC-HRMS analysis.

### Introduction

Distillation is a widely used technique in chemical analysis for characterizing materials by establishing an index of purity and for separating selected components from a complete matrix. The technique is even more widely used in preparative chemistry and throughout manufacturing industry as a means of purifying products and chemical intermediates. Distillation operations differ enormously in size and complexity from the semimicro scale to the 'thousands of tons per annum' production operations. For analytical purposes the scale employed is usually bench-level.

Numerous quoted standard specifications refer to distillation ranges as criteria of purity or suitability for use, or as indicators of performance. Published standards for analytical reagents in the AnalaR range and similar documentation by the American Chemical Society refer to distillation ranges as criteria of purity for appropriate materials.

Distillation is the process that occurs when a liquid sample is volatilized to produce a vapor that is subsequently condensed to a liquid richer in the more volatile components of the original sample. The volatilization process usually involves heating the liquid but it may also be achieved by reducing the pressure or by a combination of both. This can be demonstrated in a simple laboratory distillation apparatus comprising a flask, distillation head, condenser, and sample collector (**Figure 1**). A thermometer is included in the apparatus as shown to monitor the progress of the operation. In its simplest form this procedure results in a separation into a volatile

fraction collected in the receiver flask and a nonvolatile residue in the distillation flask. When a distillation column is incorporated in the equipment (**Figure 2**), the evaporation and condensation processes occur continuously. This results in a progressive fractionation of the volatiles as they pass up the column. The most volatile components emerge from the top of the column initially and the less volatile components emerge later. By changing the receivers throughout the course of the distillation a separation or fractionation is effected. Eventually, all the volatiles will have passed over into the sample collectors and any involatile residue present will remain in the distillation flask.

### Principles

The underlying principles are conveniently illustrated by reference to a vapor-liquid equilibrium diagram (**Figure 3**). The diagram relates to a binary mixture containing components P and Q. The lower curve gives the composition of the liquid boiling at various temperatures whilst the upper curve gives the composition of the vapor in equilibrium with the boiling liquid. Points x and y, therefore, give the boiling points of the individual components P and Q, respectively. For example, point A shows that at X degrees the vapor has a composition of approximately 90% P, whilst point B shows that the boiling liquid with which it is in equilibrium has a composition of approximately 80% P. In a continuous distillation process, such as occurs in a distillation column, liquid of composition C (90% Q, 10% P) vaporizes to vapor of composition D, which condenses to liquid of composition E. Subsequently, liquid E becomes vapor F and liquid G (composition: 50% Q, 50% P). This continuous process of vaporization and condensation occurs in the distillation column until a volatile fraction leaves the top of

**Figure 1** Simple distillation apparatus comprising distillation flask (DF), distillation head (DH), thermometer (T), condenser (C), and receiver (or collection) flask (RF). **Figure 2** Distillation apparatus including distillation column (DC). (Reproduced from Furniss BS, Hannaford AJ, Smith PWG, and Tatchell AR (1989) *Vogel's Textbook of Practical Organic Chemistry*, 5th edn., pp. 168–197. Harlow: Longman Scientific and Technical.)

the column and is removed from the process by being collected in the collection flask. At the same time the liquid in the distillation flask becomes progressively more concentrated in the involatile component.

Distillation techniques may be classified into several different types including:

- Distillation at atmospheric pressure
- Distillation under reduced pressure
- Steam distillation

**Figure 3** Vapor-liquid diagram for a binary mixture of components 'P' and 'Q', illustrating the principles of distillation (see text for details).

- Molecular distillation (short-path distillation)
- Azeotropic distillation
- Isopiestic distillation

Distillation at atmospheric or reduced pressure produces a separation according to the general principles discussed in the introduction.

Steam distillation is a means of distilling that part of a sample that is volatile in steam at a lower temperature than would otherwise be the case. This method is typically used for removing phenols from an aqueous sample. A means of introducing steam into the distillation flask must be provided.

Molecular distillation, sometimes termed short-path distillation, is used principally for compounds normally having high boiling points. In such cases, very low pressures are needed to achieve the desired low boiling points. The apparatus is constructed such that the condensing surface is located only a short distance from the distilling liquid and the pressure is reduced so that the process is governed to a large extent by the mean free path of the molecules involved. Hence the terms short-path distillation and molecular distillation.

Azeotropic distillation occurs when a mixture of two materials distils at constant composition. This technique is commonly used to remove water from samples. As an example, toluene may be added to a complex sample containing water, the distillation process results in the toluene-water

azeotrope distilling. The distillate can then be examined to determine the water content of the original sample.

Isopiestic distillation is a convenient way of producing metal-free aqueous samples of volatile acids. The 'crude' acid is placed in an open container, such as a beaker, in a desiccator containing also an open beaker of pure water. The acid vaporizes and subsequent condensation in the pure water produces an aqueous sample of the volatile acid without any of the involatile contaminants such as metals.

The alternative terms 'flash' distillation and 'fractional' distillation are sometimes used to describe some of the above procedures carried out in a particular way. Flash distillation effects a crude separation into volatiles and residue, whilst fractional distillation produces a series of 'cuts' of different volatility (or boiling point) ranges.

Additionally, there are other forms of sample purification and separation that are either a type of distillation or are related to a distillation process:

- Simultaneous distillation/extraction (see Applications section)
- Dean and Stark distillation (see Applications section)
- Simulated distillation (gas chromatographic technique)

Analytically, distillation is used for two principal purposes, firstly as a criterion of purity and secondly as a means of preparing a sample for analysis. Many specification tests include reference to a distillation range within the limits of which a stated percentage of the material of interest distills. Alternatively, distillation may be used to separate volatiles from a sample prior to a suitable analytical technique being employed on the distillate or on the residue. Standard tests are documented that involve distillation as a sample pretreatment method prior to titrimetry, potentiometry, and spectrophotometry.

It is, of course, essential if meaningful comparative results are to be obtained, that the design and use of the apparatus are standardized for such determinations.

## Apparatus

A wide variety of apparatus is available to satisfy the different distillation techniques. The appropriate design of apparatus depends upon the type of distillation to be performed, considering, for example, whether a vacuum is required or steam is needed. Descriptions of apparatus are to be found

in a number of different texts (see Further Reading). Standards referring to the design and use of distillation apparatus have been published by the British Standards Institute (BSI) and the American Society for Testing and Materials (ASTM). Simulated distillation, which is a gas chromatographic technique, is dealt with in a recent review by Robillard *et al.* and referred to in several standards.

Apparatus may be discussed in terms of the distillation flask, the distillation column, the condenser, and the collecting flask(s). By far the most effort has been expended in the design and operation of the distillation column, which is at the heart of the separation efficiency. The form of the column, its size, and the packing used are very influential upon the results that are achievable. A summary of some different types of columns is given in Table 1 and of packing in Table 2.

**Table 1** Types of distillation column

Column type	Description/comments
Dufton	An open tube into which a glass spiral fits closely
Hempel	A simple tube normally filled with a suitable packing (rings/helices) and having a side-arm near the top
Oldershaw	A column with fixed but perforated plates that maintains a fixed amount of liquid on each plate
Podbielniak	A simple tube with a wire packing to provide large contact area between liquid and vapor to effect high efficiencies
Spinning band	A tube fitted with a closely fitting spiral of PTFE or metal gauze that can be rotated at typical speeds of 600–3000 rpm as the vapor-liquid equilibrium is maintained in the column
Vigreux	A tube having pairs of indentations down its length that slope downwards and provide a large and designed surface area to enhance the liquid-vapor equilibrium

**Table 2** Distillation column packings

Packing	Description
Balls	Mostly made of glass. Columns have a tendency to flood easily
Helices	Made from metal or glass, although metal may be packed mechanically to produce a more uniform column
Rings	Usually made of glass of an appropriate size for the column but can be made of porcelain, stainless steel, aluminum, copper, or nickel. Depending upon design they can be termed Raschig, Lessing, or Dixon rings
Wire packings	Produced as 'Heli-Grid' and 'Heli-Pak' packings especially for use with Podbielniak columns

Once apparatus has been chosen carefully to compare with previously used apparatus or to conform to standards, the operation of the equipment must be considered. The following factors are among the most important to be controlled:

- The heating of the distillation flask must be carefully controlled.
- The distillation column must be operated so that it does not become flooded.
- The reflux ratio, that is, the ratio of material returning via reflux to the distillation column or the distillation flask compared to the amount presented to the condenser in unit time must be carefully controlled. The higher the reflux ratio, the purer the material collected from the distillation. Reflux ratios are controlled in simple distillation apparatus by adjustment of the heating rate and by maintaining stable thermal conditions throughout the apparatus.

## Applications

Documentation of analytical applications of distillation is widely dispersed. Distillation is used not only for the assessment of purity and characterization of volatile materials but also as a means of removing volatile compounds from an involatile matrix as part of an analytical procedure. Thus, distillation will be found in analytical procedures relating to volatile hydrocarbons, to polymers, and to environmental samples. Standards including distillation are concerned with specifying products, characterizing materials, preparing samples for analysis, and defining methods in terms of sampling, equipment, and procedures. Most advanced industrial countries have their own Standards Institutes with connections to International Organizations that promote harmonization of measurement and analysis. **Table 3** gives examples of the organizations whose standards are most frequently quoted in measurement science.

A search of the BSI and ASTM sites reveals several hundred standards involving distillation, including current and withdrawn versions, for material specifications and characterizations or for descriptions of sampling, equipment, and procedures of analytical methods involving distillation. As requirements change and analytical capabilities improve, new standards are introduced and old standards are modified or withdrawn. It is therefore advisable to consult the latest documentation prior to considering new testing methods.

**Table 3** Organizations involved with the development and promotion of standards and test methods

<i>Organization</i>	<i>Web address</i>
British Standards Institute	<a href="http://www.bsonline.techindex.co.uk">www.bsonline.techindex.co.uk</a>
American Society for Testing and Materials	<a href="http://www.astm.org">www.astm.org</a>

Hydrocarbons derived from crude oil and other fossil deposits are separated into their various fractions by using distillation and so it is not surprising that distillation is used as an analytical tool to characterize them. **Table 4** list examples of applications of distillation to hydrocarbon characterization including bituminous materials, tars, fuels, and derived organic materials.

In a similar way to hydrocarbons the purity of organic chemicals is defined by the distillation range over which they distil under carefully controlled conditions. A range of organic compounds including alcohols, esters, and chlorinated compounds are specified in this way. Examples of the associated specification standards are listed in **Table 4**.

Moisture and water content are important parameters in the processing and sale of materials from foodstuffs to petroleum based fuels. Azeotropic distillation is commonly used to determine water content using apparatus developed by Dean and Stark and an immiscible liquid such as toluene as the codistillate.

Some aspects of water quality can also be determined by methods involving distillation; these include determination of 'phenol index', nitrate content, and ammonium content.

The determination of nitrogen by the Kjeldhal method includes a preliminary distillation of the sample. Protein content can be estimated using these methods as can the determination of ammoniacal and total nitrogen in various samples including fertilizers.

As trace analysis of residual compounds in consumables has become more important, methods for extracting these compounds have been developed. A method known as simultaneous distillation extraction developed from the original work of Likens and Nickerson has been particularly popular and effective for extracting the volatiles

**Table 4** Examples of standards involving application of distillation in analysis. This table is not intended to be comprehensive but is included to show the scope of different analyses that involve analysis. Compiled by selection from websites (March 2004)

Application	Standards
<i>Hydrocarbon characteristics and purity</i>	
Tars for road purposes	BS 76
Creosote for wood preservation	BS 144
Middle distillate contamination in petroleum	BS 2000-459.1

Methods of analysis for coal and coke (total moisture)	BS 1016
Water in formulated detergents	BS 3762
Moisture in condiments and spices	BS 4585-2
<i>Water quality determination</i>	
Ammonium determination	BS 6068-2.7; ISO 5664
Phenol index determination	BS 6068-2.12; ISO 6439
Inorganic total fluoride determination	BS 6068-2.48
<i>Miscellaneous methods involving distillation</i>	
Residue from essential oils after distillation	BS 5991
Sulfur dioxide in fruit and vegetable juices	BS EN 13196
Determination of boron in steel	ISO 13900

from foods and plant materials, and the herbicide and pesticide residues in agricultural products. The method involves steam distilling the compound of interest from an aqueous suspension of the crude sample while the condensed steam is continuously extracted with an immiscible organic solvent refluxing within the apparatus. The design of the apparatus allows the volatiles that are extracted from the condensed water to be flushed into the flask containing the organic solvent. After a previously determined time of extraction, the apparatus may be disassembled and the organic solvent removed by evaporation from the now concentrated extract. Further analytical techniques can be used to identify and quantify the components of the residue according to the particular requirements.

Distillation is an accepted method of material purity specification when carried out according to standard and agreed procedures. It is also a method of sample pretreatment prior to analysis by other methods including spectroscopy, titrimetry, or potentiometry.

## Introduction

DNA sequencing is very big business. Approximately US\$3 billion was spent in 2003 on sequencing reagents and enzymes, and on the analyzer equipment and software for automated sequence acquisition. The majority of this sequence output was determined using capillary electrophoresis (CE) technology, which has commensurately developed rapidly over the past 10 years. CE offers high resolution and high throughput, automatic operation, and data acquisition, with online detection of dyes bound to DNA extension products. Operational advances such as pulsed-field and graduated electric fields and automated thermal ramping programs as the run progresses result in higher base resolution and longer sequence reads. Advanced base-calling algorithms and DNA marker additives that utilize known fragment sizing landmarks can also help to improve fragment base-calling, increasing call accuracy and read lengths by 20–30%. Despite the high efficiency of CE sequencers, the complete delineation of the human genome and its implication for genome-wide analysis for personalized medicine is driving the development of devices and chemistries capable of massively increased sequence throughput, compared to the conventional CE sequencers. Miniaturization of CE onto chip-based devices provides all of the above facilities – a significant improvement in the speed and improved automation of analysis. New array-based sequencing devices also promise a quantum increase in efficiency. Each of these new devices provides an extremely high throughput, high-quality data, and low-process costs. This article also examines the automation and improvement of sequencing processes, DNA amplification processes, and alternative approaches to sequencing.

## High-Throughput Capillary-Array Sequencing

A CE instrument comprises two electrolyte chambers linked by a thin silica capillary 50–100  $\mu\text{m}$  in diameter, or as a fine microchannel on a silicon chip. The thin capillary rapidly dissipates heat generated by the large electric fields, stabilizing band resolution. An

online detector positioned close to the capillary outlet acquires data from the size-fractionated molecules. Typically, dyes attached to the DNA fragments are detected using laser-induced fluorescence (LIF). During the recent accumulation phase of genome research, electrophoresis-based capillary-array sequence analysis developed rapidly becoming the paradigm for DNA sequencing and providing simultaneous multiparallel analyses. Capillary-array electrophoresis is a multiplied version of conventional CE, with up to 100 parallel capillaries or channels on miniature CE chips that each simultaneously analyze individual samples (see **Figure 1**).

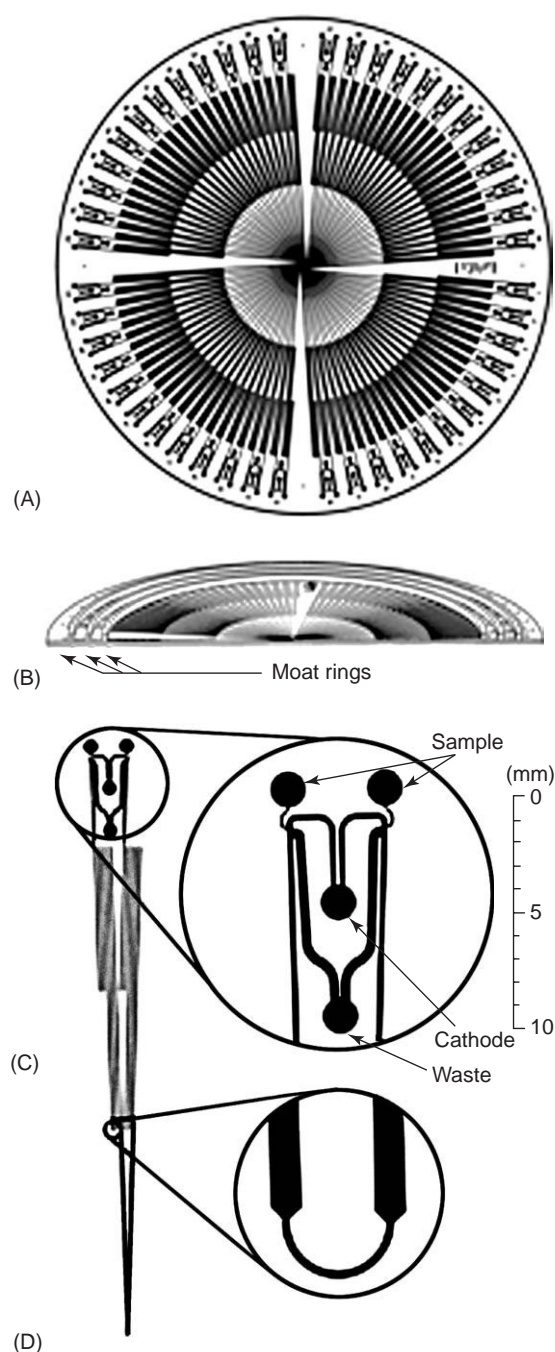

## Signal Detection Dyes

Energy-transfer dye-tagged nucleotides are efficiently incorporated into DNA by available enzyme systems and have higher sensitivity and better spectral discrimination than earlier fluorophore dyes. Two-dimensional direct-reading spectrographs can analyze fluorescence simultaneously from each of the collimated capillary dye streams passing across a charge-coupled device (CCD) camera as the stream emerges from the end of each capillary. Devices with 384 capillaries process sequence data from as many as 2500 samples per day, with each sequence presented as a stained-glass plot representing the dye-space electropherogram of each capillary. New sensitive photometric devices can now detect extremely low numbers of signal molecules, and even single molecules. Alternative detection methods such as time-resolved fluorescence decay, electrochemical detection, chemiluminescence, and near-infrared (NIR) detectors can now be incorporated in microdevices, and recent development of efficient incorporation processes will make widespread application possible. Dye-tagged nucleotides with longer linker lengths and charge matching improve the incorporation of these bulky molecules into nascent DNA (see **Figure 2**). The positively charged linker drives unincorporated dye-terminator nucleotides in the opposite direction to the sequencing products, also eliminating the need for reaction cleanup.

## Microchip Electrophoresis Sequencing

The microchip analysis format has significant advantages over conventional CE, being 10 times faster

**Figure 1** (A) Overall layout of the 96-lane DNA sequencing microchannel plate (MCP). (B) Cut-away of the MCP (vertical view). The concentric rings form two electrically isolated buffer moats that lie above the cathode and waste ports. (C) Expanded view of the injector. Each doublet has two sample reservoirs and common cathode and waste reservoirs. The sample to the separation channel arm is  $85\ \mu\text{m}$  wide, and the waste to separation channel arm is  $300\ \mu\text{m}$  wide. The separation channel is  $200\ \mu\text{m}$  wide. (D) Expanded view of the hyperturn region. The turns are symmetrically tapered with length  $100\ \mu\text{m}$ , turn channel width  $65\ \mu\text{m}$ , and a radius of curvature  $250\ \mu\text{m}$  (Reproduced with permission from Paegel BM, Blazej RG, Wedemayer GJ, *et al.* (2002) *Proceedings of the National Academy of Science USA* 99: 574–579; © National Academy of Sciences, USA.)

and using submicroliter volumes of analysis reagents. Strand-displacement amplification (SDA) and rolling-circle amplification are isothermal *in vitro* methods for amplification of a specific DNA sequence to concatomer lengths. Burns and colleagues elegantly demonstrated the extremely rapid DNA analysis using an integrated microchip system incorporating both DNA amplification and CE separation of SDA products. Significant advances in the amplification and detection of single DNA template molecules on integrated devices are providing unprecedented levels of sensitivity. New constriction-channel designs improve fragment resolution and increase the scope for longer pathlengths, permitting single base resolution over longer fragments. Revolutionary two-dimensional separation CE devices represent a new paradigm for sequence analysis, when coupled with two-dimensional array detectors. More conventionally, new low-voltage closed-loop CE devices offer the promise of handheld, or readily transportable analysis instruments. Microfabricated multireflection absorbance cells for microchip-based CE have also been built with 5- to 10-fold enhanced sensitivity over single-pass devices. Currently, these schemes are being built into devices with hundreds of capillaries to achieve high speed, extremely high throughput, and higher detection sensitivity. Microdevices that require no operator intervention and which integrate sample purification, sample amplification, amplicon product purification, and DNA sequencing by CE have been developed (see Figure 3). Unincorporated dye terminators are electrically separated from sequencing products under high voltage into a waste channel, prior to diverting the sample into a separation capillary for size resolution and sequence analysis. Micro-machined sheath-flow cuvettes that precisely control both capillary alignment and matrix flow. And confocal LIF systems with one lens for both excitation and detection optics, scanning continuously across a bundle of capillaries, can provide both longer reads and more accurate base-calling. Other nanoreactors, with serial electrodes that provide for high ‘sweeping field’ separation using low-voltage supplies suited to handheld devices, can achieve polymerase chain reaction (PCR) amplification in 15 min and CE analysis in 2 min. The nanoreactors can be interfaced either to microelectrophoresis chips or capillary gel tubes via micromachined capillary connectors or zero-dead volume unions, and signals are detected using a NIR fluorescence detector. Sequencing reactions from a small ( $\sim 60\ \text{nl}$ ) volume reactor could be coupled directly to a capillary gel column for separation with minimal loss in the efficiency of the separation process and capable of single-base resolution to  $>450$

**Figure 2** Synthesis of single dye-labeled oligo-trimethyllysine-modified 2',3'-dideoxynucleoside-5'-triphosphates. (Reprinted with permission from Finn PJ, Bull MG, Xiao H, *et al.* (2003) *Nucleic Acids Research* 31: 4769–4778; © Oxford University Press.)

bases. These devices permit complete CE analysis in an easily transportable format.

## Solid-Phase and Array-Sequencing Devices

The demand for ultrahigh throughput sequencing for personal medicine is driving the development of nonelectrophoretic methods for sequencing multiple single molecules in parallel. These devices use wide-ranging technologies such as array-based solid-phase techniques, sequencing by synthesis methods, ultra-sensitive optics, and mass spectrometry (see **Table 1**). If current process problems are solved, these new nanosequencing technologies could markedly increase in sequence capacity required by genome-sequencing projects and large genome resequence analysis programs.

## Single DNA Molecule Sequencing

The need for analysis of single DNA molecules has coincided with the development of technologies capable of single molecule sensitivity. The miniaturization

of chip CE systems with nanochannels  $< 1 \mu\text{m}$  allows analysis to be undertaken on limited numbers of molecules at pico- and nanomolar concentrations, with amplification and detection of signals from single template molecules. Single DNA molecule imaging can achieve simultaneous analysis of up to 100 000 distinct molecules every second. Several solid-state methods for single DNA molecule sequencing have been reported recently, again with promise of highly parallel, genome-scale efficiencies. 'Single-molecule sequencing with exonuclease' comprises the serial digestion of a single-DNA strand attached to a solid surface or microchannel surface. The fluorescent-tagged nucleotide subunits are sequentially released, then collected, and detected. The method demands highly efficient enzymatic incorporation of labeled analogs at each subunit nucleotide position. US Genomics offer another potential solution, with technologies that can directly analyze individual molecules of DNA at ultrahigh throughputs without amplification (e.g., PCR). The process of direct analysis begins with fluorescently tagging the sample genomic DNA at specific nucleotide sequence motifs. The sample is then interrogated using several lasers as it passes through a nanofluidic

Current opinion in Biotechnology

**Figure 3** A microfabricated 'sequencing factory-on-a-chip'. An individual subclone is sorted and directed to a PCR amplification chamber. Single-cell amplification is followed by template purification. The purified template is moved to a thermal cycling reactor for generation of sequencing extension fragments. The extension fragment products are isolated, concentrated, and then injected into an electrophoretic microchannel for length analysis. The total estimated process volume from cell to called bases is  $\sim 1 \mu$ l. (Reprinted with permission from Paegel BM, Blazej RG, and Mathies RA (2003) Microfluidic devices for DNA sequencing: Sample preparation and electrophoretic analysis. *Current Opinion in Biotechnology* 14: 42–50; © Elsevier.)

analyzer instrument, with thousands of molecules analyzed per minute. For DNA analysis, this represents a throughput of 10–30 million base pairs per second, with each molecule detected by the laser excitation of the fluorescent tags on the molecule.

## Nanofluidic Barrier Sequencing

Sequencing methods employing physical techniques and nanoscale fluidics combined with ultrasensitive optical systems are being developed to sequence single molecules, one molecule at a time. The nanodevices sort DNA molecules by using openings or pores or forests of pillars that are less than the 'radius of gyration' of the DNA fragments, just large enough for DNA molecules to run through in single file. When a DNA molecule is placed outside a 'forest' of tiny pillars arranged in a square grid and the molecules forced to move into the grid by an electric field, the DNA must uncoil to pass through. By varying the electric field pulse, the length of the DNA strands that are collected in the grid can be controlled and thus separated by size (length). When a mix of DNA fragments is driven electrically along a channel with several such barriers, fragments of different lengths will arrive at the far end in a series of bands not unlike those seen in conventional gel electrophoresis separations. Single-molecule sequencing (SMS) promises to radically improve DNA sequencing as it is potentially 10 000 times faster than current production systems that rely on single lanes. It can potentially start with genomic DNA reducing the need for sample preparation. SMS read lengths are also potentially significantly longer than those obtained from gel electrophoresis systems. Longer read-lengths will simplify sequence reconstruction and reduce the total number of runs required to get full coverage of the genome. Uniquely, SMS sequencing can directly detect haplotypes over several polymorphisms.

## Massively Parallel Signature Sequencing

Massively parallel signature sequencing combines techniques developed for expression analysis with data accumulated from representative but uncharacterized cDNA libraries. The system comprises microbeads with 32-mer tags comprising strings of eight 4-mer 'words' that hybridize amplified cDNA library targets. The beads each hybridize  $\sim 100\,000$  molecules of a unique cDNA, the beads are then sorted on an FACS analyzer, and distributed in a micromachined flow cell into a planar array. The sequence of each immobilized cDNA bead is then 'read' successively by the restriction enzyme *BbvI* after linking of encoded 'adapters' to the end of each exposed specific cDNA overhang and by a second set of fluorescently labeled 'decoder' oligonucleotides. The system has large capacity for sequence analysis, with some one million cDNA-coated beads being

simultaneously analyzed in a single machine experiment within several days, with over  $\sim 20$  bases read per bead. This technology provides a 'signature' for each cDNA rather than full-length sequence analysis.

## Sequencing by Synthesis

'Sequencing by synthesis' is a method common to primer extension methods such as single nucleotide primer extension (SNUPE) and pyrosequencing, in which a unitary base addition chemistry that allows single nucleotide additions to growing chains to be monitored on each oligonucleotide feature, simultaneously with the addition of one of four differentially labeled, terminating nucleotides. Church and colleagues initiated the integration of solid-state DNA sequencing using polymerase colonies ('colonies') and cycles of fluorescent dNTP incorporation with high signal sensitivity, which allow multiple colonies to be sequenced in parallel (see **Figure 4**). Large-scale arrays

of discrete 'colonies' can be extended cyclically, bringing closer cost-effective genome-scale single array sequencing. 'Fluorescence *in situ* sequencing' involves the addition of one nucleotide; the extended fragments are then all detected simultaneously using CCD optics, the terminating moiety and fluor-tag are then removed chemically from each attached nucleotide ready for the addition of the next nucleotide to each chain in the following cycle. The series of base additions (e.g., C A T G C A T G, ...) is interrupted by scanning (for data acquisition) and chemical treatment of slides to remove signal prior to the next extension step. Ideally, the polymerase catalyzed strand extensions continue for 30 nucleotides or more.

The technology company 454 Life sciences has developed a solid-phase parallel microarray system of microfluidic wells in which  $10^8$  oligonucleotide molecules per square centimeter are used to capture complementary DNA fragments. Pyrosequencing reactions are simultaneously monitored on each

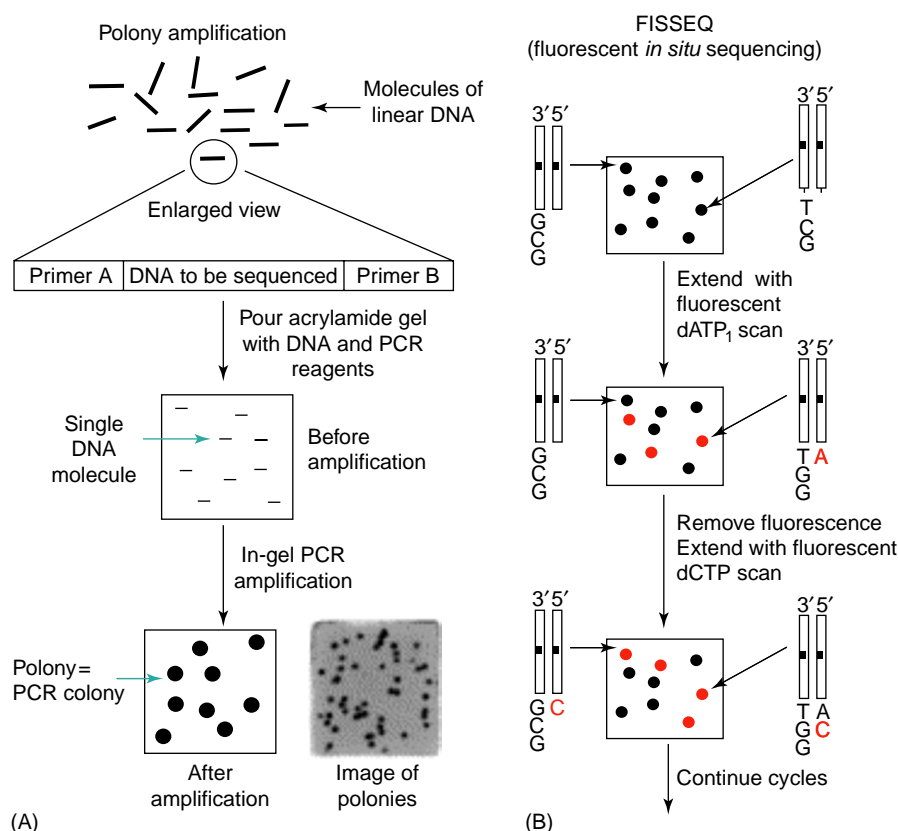

well-attached molecule, for each base addition. Solexy Pty Ltd. is another company, which sequences on arrays using a nanofeature format innovation such as zero-wave guide, a device confining optical excitation and detection to the few zeptoliters of fluid surrounding the polymerase, and the identification of nucleotides by fluorescent labels attached to the  $\gamma$ -phosphate leaving group of the dNTP. These two different arrayed analysers are expected to develop sequencing rates of  $10^8$  base-reads per day, the equivalent of a billion-lane sequencer that reads the sequence of each molecule at the speed of the addition reaction. Although currently the efficiency and uniformity of extension is poor, it is expected that if each molecule could be extended by an average 50 nucleotides, it will allow parallel discovery and detection of genetic variation on  $10^8$  molecules that can be aligned to known reference sequence (such as the human genome). 'Sequencing by synthesis' may permit *de novo* sequencing of entire genomes of low repetition, such as phage, virus, and bacterial genomes. In August 2003, 454 Life Sciences announced that 'sequencing by synthesis' technology

was used to sequence the entire 35 kb genome sequence of adenovirus, which due to its low complexity is amenable to this analysis.

## Sequencing by Mass Spectrometry

Mass spectrometry is used to determine the sequence of a polynucleotide by analysis of the atomic masses of a series of polynucleotide subfragments derived by the partial and uniform fragmentation, or by the uniform extension of the polynucleotide. The polynucleotide subfragments are released from a solid phase and analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). The techniques include partial enzymatic cleavage, chemical cleavage, base-specific cleavage of PCR products, and primer extension Sanger sequencing SNUPE methodologies. Nucleotide analogs are used widely during DNA sequence analysis by mass spectrometry – to modify polynucleotide electrochemistry and stabilize the *N*-glycosidic linkages, to block base loss and subsequent random backbone cleavage, or to introduce

**Figure 4** (A) Polony amplification. A library of linear DNA molecules with universal priming sites is PCR amplified within a polyacrylamide gel. Each single template molecule gives rise to a polymerase colony or 'polony'. (B) Fluorescent *in situ* sequencing. Polonies are denatured, and a sequencing primer is annealed. Polonies are sequenced by serial additions of a single fluorescent nucleotide. site-specific backbone weakness for controlled fragmentation. Wolfe and others have employed analogs such as 7-deaza analogs, 5'-amino-5'-deoxy- and 5'-amino-2',5'-dideoxy-analogs, and stable mass isotope tags to substitute for particular nucleotides (see **Figure 5**). These nucleotide analogs introduce differential mass properties, or differential stability into the DNA subfragments that improve the mass separations. Boranophosphate-modified nucleotides incorporated randomly into DNA can reveal sequencing ladders directly by exonuclease digestion. Borano analogs form standard Watson–Crick base pairs, but are preferentially and uniformly cleaved compared to native nucleotides at their phosphoribose backbone. Similarly, acids and bases can cleave dideoxy and amine-modified analog backbones generating sequencing ladders, which may be analyzed by mass.

## Sequencing of Problematic DNA

Several new methods to overcome DNA motifs that are refractile to conventional sequencing have been developed. Transcriptional sequencing using RNA polymerases and dye-tagged ribonucleotides improve the sequencing of GC-rich regions, simple sequence repeats, hairpins (inverted repeats), tandem repeat DNA templates, and gap-closing in draft sequencing data. 'Thermofidase' is another highly effective sequencing system using engineered DNA polymerases and chimeric thermostable 'DNA polymerase' and 'topoisomerase V' in combination with cycle sequencing and modified oligonucleotides. These chimeric polymerases resist inhibitors and are also particularly effective for sequencing regions of GC-rich DNA and highly repeated centromeric DNAs. Another method for tackling of poly A- and AT-rich tracts uses the excision or truncation of the A/T-rich region. Poly A tails are shortened by type IIS restriction enzymes such as *GsuI* before cDNA cloning.

Whilst another method relies on the slippage of mung bean nuclease, which digests A/T-rich double-stranded DNA into a set of deletion fragments that can then be cloned and sequenced. 'Sequencing aided by mutation' is a radically different method that overcomes sequencing difficulties caused by 'problematic motifs' – regions where local sequence characteristics hinder existing sequencing technologies. Here, problematic motifs and regions are mutated in a random manner, sufficiently to overcome the obstruction to sequencing or cloning. The random locations of the mutations cause the copies of the region to have different sequences. The DNA sequences determined from a low number of the altered copies are then analyzed using Bayesian methods to reconstruct the original wild-type sequence, with cost efficiencies and accuracy similar to conventional sequencing.

## Introduction

A knowledge of the fate of a drug, its disposition (absorption, distribution, metabolism, and excretion; ADME) and pharmacokinetics (PK) (the mathematical description of these processes) is important throughout pharmaceutical research and development. The aim of a typical pharmaceutical company is to identify and develop good orally active candidate molecules that have suitable potency and selectivity against a target, sufficient oral bioavailability, metabolic stability, and duration of action. The importance of ADME/PK has been highlighted in surveys that have revealed that the main causes of failure during development are unacceptable clinical efficacy, toxicity, and poor PK. In fact, as much as 40% of all failures have been attributed to poor PK. *In silico* (computer-based), *in vitro* (cell-based), and *in vivo* (animal-based) techniques are

available for investigating the ADME/PK of new chemical entities (NCEs). Both the scientific concepts underpinning this discipline and the techniques and rationale employed will be detailed in this article.

## The Science of ADME/PK

All drugs have the potential to produce unwanted effects. In drug research and development it is essential to select chemicals that have a margin of safety between the dose that produces the desired (therapeutic) effects and the dose that produces undesired (toxic) effects.

The investigation of ADME/PK aids in the discovery and selection of new drugs, supports safety assessment, and helps define conditions for effective use in patients. The main objectives of ADME/PK studies can therefore be summarized as shown in Table 1.

### Drug Absorption

For a drug to work it must be a solution at the site of delivery. If orally administered it must dissolve in the lumen of the small intestine. Once in solution it must

**Table 1** Main objectives of ADME/PK studies

To characterize the basic pharmacokinetic parameters of a test substance
To understand the mechanism of action of a drug
To support toxicology studies
To validate the appropriateness of the animal species used in toxicology
To establish margins of safety between the therapeutic and toxic effects
To optimize dosage regime (size, formulation, frequency)
To establish target organs/modes of absorption and elimination
To establish nature of metabolism
To provide data for regulatory authorities

be absorbed through the walls of the intestine and subsequently cross the barriers between the blood stream and the site of action. Absorption can therefore be defined as the net transfer of a substance from its site of administration to the site of effect.

The entry of many orally administered drugs into the systemic circulation is dependent on their tendency to partition into lipid (lipophilicity). Lipophilic properties facilitate a compound's penetration of lipid membranes and transportation in blood lipoproteins but their lower water solubility reduces urinary excretion. In addition, lipophilic compounds are more likely to undergo extensive metabolism.

The degree of ionization of a drug can dictate how lipid soluble it is. Ionization, as measured by the dissociation constant ( $pK_a$ ), can vary with the pH of the environment. When the pH of a solution is equal with  $pK_a$  the concentration of the ionized species is the same as that of the unionized species. As many drugs are either weak acids or weak bases, the degree of ionization can impact on their absorption, distribution, and excretion characteristics as shown in Figure 1.

The solubility of a compound is a barrier that limits its concentration in a solution and therefore the amount of material available for absorption. A compound's crystal type (polymorph), its particle size, wettability, and the use of solubilizing agents in formulations can all influence solubility. Also, the formation of salts, esters, and complexes with a compound can improve its solubility. Solubility is a key parameter for determining the dissolution rate of compounds, a more informative measure that takes into account the form and particle size distribution in a particular medium.

A number of mechanisms of absorption exist but the most important of these, for the vast majority of compounds, is passive diffusion where the movement of compound is driven by the concentration gradient that can occur between cell junctions (paracellular)

or through cells (transcellular). Lipophilic compounds tend to cross the plasma membrane most readily and utilize the transcellular route, while hydrophilic compounds tend to utilize the paracellular route. In addition, some substances can be transported by an active system either with or against a diffusion gradient. An important transporter protein, P-glycoprotein (P-gp), is present in the plasma membrane of many cells and is responsible for the efflux of a wide range of substrates. The presence of a significant P-gp efflux capacity in the intestinal lumen reduces the overall absorption of many compounds. The main mechanisms of transport that can occur in the intestinal epithelium are shown schematically in Figure 2.

The small intestine is folded into villi and microvilli which increases surface area many times. Even poorly soluble compounds often undergo reasonable absorption because of the large surface area. Absorption can be reduced if blood flow in the gastrointestinal tract is insufficient to maintain 'sink conditions' or if transit times within the tract are too rapid.

### Drug Bioavailability

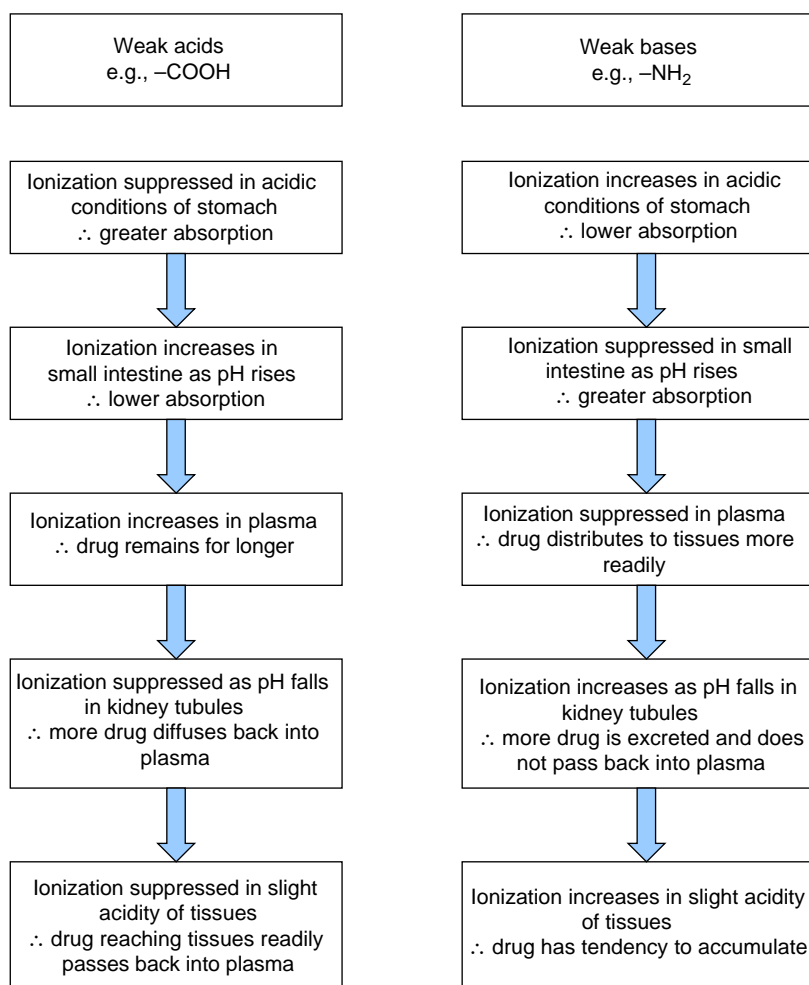

Following absorption, first-pass metabolism can reduce the total exposure of the body to drug. First-pass metabolism refers to any loss of the administered material by transmucosal or hepatic means after absorption and before reaching the systemic circulation, and this is shown schematically in Figure 3.

Bioavailability is a term used to describe the systemic availability of drug and can be defined as the rate and extent of appearance of unchanged drug in the systemic circulation following an extravascular (e.g., oral) dose. Experimentally, it is determined as the fraction of the maximal levels of drug present in the systemic circulation after an intravenous dose. It takes into account both absorption and metabolism and is dependent on area under the curve (AUC), peak concentration achieved ( $C_{max}$ ), and time to reach peak concentration ( $t_{max}$ ). It is generally expressed as a percentage and is represented by eqn [1]:

$$\% \text{Bioavailability} = \frac{\text{AUC}_1 \times \text{Dose}_2}{\text{AUC}_2 \times \text{Dose}_1} \times 100 \quad [1]$$

where 1 refers to an oral dose and 2 refers to an intravenous dose.

The assessment of many PK parameters depends upon the accurate measurement of AUC. Although software is used routinely to do this, the calculations are straightforward and are based on the sum of

**Figure 1** Consequences of ionization for weak acids or bases during their passage through the body.

**Figure 2** Multiple mechanisms of transport through the intestinal epithelium.

**Figure 3** Schematic diagram to show sites of first-pass metabolism.

trapezoid areas under the concentration versus time curve for each sampling interval (trapezoidal rule).

As pharmacological effect depends upon the quantity of unchanged drug reaching the target organ and its residence time, it is evident that changes in absorption and metabolism will lead to changes in bioavailability and therefore activity.

Relative bioavailability (bioequivalence) is the comparison of the rate and extent of drug appearance in the systemic circulation when one formulation is compared with another. When two or more formulations of the same drug produce statistically indistinguishable rates and extents of appearance they can be said to be bioequivalent.

### Drug Distribution

Drug distribution can be defined as the (reversible) transfer of drug around the body. This is usually very quick within the vascular system but variable into tissues, being dependent on a number of factors including blood perfusion rate, drug diffusion rate, plasma protein binding, and tissue binding.

The amount of drug distributed cannot normally be measured directly and so is inferred from PK analysis of the plasma concentration–time profile utilizing eqn [2]. The apparent volume of distribution ( $V_d$ ) can be defined as the volume that a drug would occupy were the drug present in all tissues at the same concentration as observed in the plasma:

$$V_d = \frac{\text{amount in body (dose)}}{\text{plasma concentration } (C_0)} \quad [2]$$

where  $C_0$  is the plasma concentration if drug had been instantaneously distributed into its final volume following an intravenous dose;  $V_d$  can vary from 0.05 to 800 l kg<sup>-1</sup>. The lower values are usually for drugs that remain in the plasma compartment, i.e., they are hydrophilic and/or tightly bound to plasma. The higher values are for drugs that have a high affinity for tissues.

When a membrane is not a substantial barrier to a drug, the rate of perfusion of the tissue becomes the limiting factor; this is commonly the case for small lipophilic molecules. Distribution occurs rapidly in highly perfused organs (e.g., lungs) and slowly in poorly perfused organs (e.g., fat). A diffusion rate limitation occurs when a tissue membrane is a substantial barrier to the movement of drug, e.g., the blood–brain barrier has poorly permeable capillary membranes that are effective in blocking the passage of many drugs into the brain. The rate of distribution is also dependent on total body mass; therefore, distribution equilibrium is likely to be achieved faster in smaller species.

As the most abundant plasma protein is albumin (which prefers to bind acidic drugs), the total binding for acidic drugs can be very high (greater than 99.9%) and therefore the volumes of distribution can be very low. Less abundant but still important is the plasma protein  $\alpha$ 1-acid glycoprotein that tends to bind basic drugs. The extent to which a drug binds is governed by an equilibrium (or affinity) constant, the concentration of the protein and of the drug. Therefore, as only unbound ‘free’ drug will pass through membranes, the dissociation rate can control the rate of distribution. In addition to plasma protein binding, drugs can bind to various sites within tissues. Lipophilic weak bases, for instance, have a high affinity for the acidic phospholipids, which make up biological membranes, and therefore they tend to have high volumes of distribution.

Drug distribution is related, as shown in eqn [3], to the plasma elimination half-life ( $t_{1/2}$ ), the time it takes for the plasma concentration or the amount of drug in the body to be reduced by 50%:

$$t_{1/2} = \frac{V_d}{Cl_p} \times 0.693 \quad [3]$$

where  $Cl_p$  refers to plasma clearance (see eqn [6]).

The  $t_{1/2}$  will therefore increase if  $V_d$  increases or  $Cl_p$  decreases, and if a drug has a high  $V_d$  and a long  $t_{1/2}$  this can indicate tissue accumulation.

### Drug Elimination

Drug elimination can be defined as the (irreversible) transfer of a drug from the site of measurement (usually plasma or blood) by either excretion (e.g., renal, biliary, pulmonary, sweat and milk excretion) or metabolism.

Renal excretion is particularly important. Glomerular filtration removes unbound low molecular weight compounds and active secretion and passive reabsorption processes occur throughout the kidney tubules depending on a drug’s ability to cross lipid

membranes and degree of ionization. The net rate of renal excretion can be estimated using eqn [4]:

$$\begin{aligned} \text{Net rate of renal excretion} = & \text{Rate of filtration} \\ & + \text{Rate of secretion} \\ & + \text{Rate of reabsorption} \quad [4] \end{aligned}$$

Biliary excretion results in the elimination of drugs in the bile and is determined by molecular weight. Little biliary excretion occurs for molecules with molecular weight less than 300 and very large molecules such as proteins. The approximate molecular weight thresholds above which drugs can be excreted directly in bile are higher in man and monkey (500) than rabbit (475), guinea-pig (400), and rat and dog (325). It is important to note that because the threshold for rat and dog, the usual toxicology species, is somewhat lower than for man, this can lead to species differences for compounds of intermediate molecular weight.

Enterohepatic recycling is where compounds are returned to the gut via the bile and then reabsorbed. This process can lead to very long  $t_{1/2}$  values, e.g.,  $t_{1/2}$  for digoxin in dogs is raised from 6 to 14 h by recycling.

Expired air is an important route of elimination for anesthetics and some volatile compounds are readily excreted in sweat. The elimination of compounds in mother's milk can lead to high exposures for the baby when it is their only source of nourishment. The mucosal secretion of drug back into the gut can also be an important route of elimination.

Clearance is an important property of a drug, and as already indicated in eqn [3], reducing clearance can extend the  $t_{1/2}$ . It can be defined as the volume of blood (or plasma) from which all drug is removed in unit time and depends upon the flow of blood through organs and their extraction ratio (ER). The ER can be calculated from drug concentrations as shown in eqn [5]:

$$ER = \frac{C_{in} - C_{out}}{C_{in}} \begin{cases} \text{If organ extracts nothing } ER = 0 \\ \text{If organ extracts everything } ER = 1 \end{cases} \quad [5]$$

where  $C_{in}$  and  $C_{out}$  are the concentrations of drug entering and leaving the organ, respectively. In the case of the liver,  $C_{in}$  is the concentration in the hepatic portal vein blood and  $C_{out}$  the concentration in the systemic circulation.

The total clearance is the sum of the clearances in all organs. If the clearance of drug from blood/plasma approaches the blood/plasma flow through the liver, this indicates that the drug is likely to undergo hepatic first-pass removal. An estimate of  $Cl_p$

can be obtained from intravenous dosing data using eqn [6]:

$$Cl_p = \frac{\text{DOSE}}{\text{AUC}} \quad [6]$$

During a drug's development it is important to investigate the effect on exposure of changing the dose, and to prove that clearance is dose-independent. When  $Cl_p$ ,  $V_2$ , and  $t_{1/2}$  remain constant over a dose range and over time, a drug can be said to have linear PK. If an elimination process becomes saturated, AUC tends to increase with dose more than one would expect, if absorption or plasma protein binding are saturated, AUC tends not to increase with dose as much as one would predict.

Knowing the  $Cl_p$  and  $t_{1/2}$  of a drug one can modify the size and frequency of doses. Doses should be given at repeated intervals such that the 'rate in' equals the 'rate out'. If doses are too high and frequent, then toxic levels may be achieved. If doses are too low and infrequent, then the drug may prove ineffective. **Figure 4** shows the ideal situation where plasma concentrations reach a plateau and the same maximum ( $C_{max}$ ) and minimum ( $C_{min}$ ) concentrations are reproduced within the therapeutic window, i.e.,  $C_{min}$  is kept above the minimum effective concentration and  $C_{max}$  below the minimum toxic concentration.

While PK data indicate what the body does to the drug over time, pharmacodynamic (PD) data indicate what the drug does to the body over time. PK/PD modeling involves linking PK and PD data to assess the response-time relationship. The predictivity of models varies with their complexity and the type of data available. Often, response does not track directly with concentrations with the greatest effect being observed well after maximal concentrations have occurred. Generally, the most reliable models depend on the measurement of 'free' levels at the site

**Figure 4** Plot of plasma concentration versus time following the application of an 'ideal' dosing regimen.

of drug action and the accurate and precise measurement of drug effect.

### Drug Metabolism

Drugs are metabolized if the body is unable to excrete them unchanged. The main site of metabolism is the liver. The principal reason for metabolism is to increase the water solubility and hence the excreatability of the compound. It is important to note that many of the enzymes involved in drug metabolism have evolved for the metabolism of naturally occurring compounds and only attempt to metabolize drugs because they resemble them in some way. The route of metabolism of a drug can determine whether it shows any pharmacological or toxicological activity. Usually, the metabolism of a drug reduces its toxicity but certain metabolites (usually short-lived, reactive intermediates) are able to produce toxic effects. Studying metabolism allows species comparison of metabolite patterns to validate toxicity studies, to help understand PK/PD, and to allow extrapolation to man. The PK of metabolites along with that of the parent compound may help to give a better overall understanding of the observed effect (desired or undesired).

The main routes of metabolism are the chemical reactions of oxidation, reduction, hydrolysis, and conjugation. These can be divided into two phases: phase I (or functionalization reactions) and phase II (or conjugative reactions).

**Phase I metabolism** Phase I reactions (mainly oxidation, reduction, and hydrolysis) act as a preparation of the drug for the phase II reactions, i.e., a chemically reactive group is produced or uncovered on which the phase II reactions can occur, e.g.,  $-\text{OH}$ ,  $-\text{NH}_2$ ,  $-\text{SH}$ ,  $-\text{COOH}$ . Most toxic metabolites are produced by phase I reactions. The P-450 isoenzymes (CYP enzymes), known collectively as the mixed function oxidase system, are found in the endoplasmic reticulum of many cells (notably those of liver, kidney, lung, and intestine) and perform many of these different functionalization reactions. The system requires the presence of molecular oxygen and co-factor nicotinamide adenine dinucleotide phosphate (NADPH) as well as cytochrome P450, NADPH-cytochrome P450 reductase, and lipid.

Cytochrome P450 is a heme-containing protein embedded in the endoplasmic reticulum, which exists in multiple forms and has a molecular weight of 45 000–55 000. The heme (Figure 5) is noncovalently bound to the apoprotein and serves as both the oxygen and substrate-binding site.

**Figure 5** Ferroporphyrin IX heme prosthetic group.

The oxidation reaction catalyzed by CYPs conforms to the stoichiometry shown in eqn [7]:

where RH represents an oxidizable drug substrate and ROH is the hydroxylated metabolite. The source of the reducing equivalent ( $2\text{H}^+$ ,  $2\text{e}^-$ ) is either NADPH or NADH mediated by a flavoprotein (FAD).

Three CYP families, CYP1, CYP2, and CYP3, account for ~70% of human hepatic microsome CYPs with CYP3 accounting for ~30%. These CYPs are the major ones responsible for the metabolism of commonly prescribed drugs. Specifically, the most important isoforms are CYP1A1, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. CYP3A4 has the widest substrate specificity and is estimated to be involved in the metabolism of ~50% of drugs used in humans.

Oxidations can occur at both aliphatic and aromatic carbon atoms. This leads to increased water solubility because of an increase in hydrogen bonding and ionizability. Oxidations can also occur at nitrogen and sulfur atoms with the formation of nitrogen and sulfur oxides. Another common phase I reaction is dealkylation; the removal of an alkyl group from either an oxygen producing an alcohol, or a nitrogen atom producing an amine. Reduction reactions are generally inhibited by oxygen and occur mainly under anaerobic conditions, e.g., in the gastrointestinal tract. Hydrolysis is catalyzed chiefly by esterases and peptides. Some of the most common phase I oxidation, reduction, and hydrolysis reactions are summarized in eqns [8]–[20].

### Oxidations

#### *Aromatic hydroxylation*

For example, phenobarbital → *p*-hydroxyphenobarbital.

*Aliphatic hydroxylation*

For example, pentobarbital → pentobarbital alcohol.

*Dealkylation*

For example, imipramine → desmethylinipramine (*N*-dealkylation) and codeine → morphine (*O*-dealkylation).

*Oxidative deamination*

For example, amphetamine → phenylacetone + NH<sub>3</sub>.

*N-oxidation*

For example, chlorpromazine → chlorpromazine N-oxide.

*S-oxidation*

For example, chlorpromazine → chlorpromazine S-oxide.

*Desulfuration*

For example, thiopental → pentobarbital.

*Epoxidation*

For example, benzopyrene → benzopyrene epoxide.

*Alcohol oxidation*

For example, ethanol → ethanal.

**Reductions**

*Azo reduction*

For example, prontosil → sulfanilamide + triamino-benzol.

*Nitro reduction*

For example, *p*-nitrobenzoic acid → *p*-aminobenzoic acid.

**Hydrolysis**

*Ester hydrolysis*

For example, procaine → *p*-aminobenzoic acid + diethylaminoethanol and aspirin → salicylic acid + acetic acid.

*Amide hydrolysis*

For example, phenacetin → phenetidin + acetic acid.

**Phase II metabolism** Phase II conjugation reactions give rise to the bulk of the inactive, excreted products of a drug and involve the addition of an endogenous molecule to a compound. Generally, conjugation results in a large increase in water solubility and molecular weight, which encourages biliary excretion. Importantly, conjugation also leads to the inactivation of many reactive phase I products. The most common enzymes and functional groups involved are listed in Table 2.

Glucuronidation occurs at oxygen and nitrogen atoms and is one of the most common phase II reactions. It can occur with alcohols, phenols, hydroxylamines, carboxylic acids, amines, sulfonamides, and thiols and utilizes the energy-rich co-factor uridine diphosphoglucuronic acid (UDPGA).

Sulfation occurs at oxygen atoms. It can occur with phenols, alcohols, amines, and thiols and utilizes the energy-rich co-factor 3'-phosphoadenosine-5'-phosphosulfate (PAPS). Competition with glucuronidation for substrates can occur and in general sulfate conjugation predominates at low substrate concentrations and glucuronide conjugation at high concentrations, due to the kinetics of the two reactions and the more limited supply of PAPS compared to UDPGA.

Acetylation results in the addition of a CH<sub>3</sub>CO group to nitrogen atoms to give an amide and although this results in no great change in water solubility the nitrogen is 'inactivated'. It utilizes the co-factor acetyl (CoA).

Glutathione conjugation is recognized as a protective compound useful for the removal of potentially toxic electrophilic compounds. It can occur

with epoxides, haloalkanes, nitroalkanes, alkanes, and aromatic halo- and nitro-compounds. The levels of glutathione in the body are finite and depletion following an overdose with a compound that undergoes this form of metabolism can result in toxicity due to the presence of large amounts of unconjugated reactive electrophiles, e.g., paracetamol.

**Table 2** Principal conjugation reactions

Reaction	Enzyme	Functional group
Glucuronidation	UDP – glucuronyltransferase	–OH –COOH –NH <sub>2</sub> –SH
Glycosidation	UDP – glycosyltransferase	–OH –COOH –SH
Sulfation	Sulfotransferase	–NH <sub>2</sub> –SO <sub>2</sub> NH <sub>2</sub> –OH
Methylation	Methyltransferase	–OH
Acetylation	Acetyltransferase	–NH <sub>2</sub> –SO <sub>2</sub> NH <sub>2</sub> –OH
Glutathione conjugation	Glutathione-s-transferase	Epoxide Organic halide

A good example of a compound undergoing a number of key conjugation reactions is *p*-aminosalicylic acid (**Figure 6**).

All tissues have some metabolic capacity, but greatest activity is seen in the liver, gastrointestinal lumen plus microflora, kidney, and blood. Many factors can affect drug metabolism including the dose level (exposure) and route, species and genetic differences, age, sex, diet, environment, disease, and the inhibition and induction of enzymes. An important exposure-related effect sometimes seen at high doses is when a metabolizing enzyme becomes saturated causing a change in drug:metabolite ratios and an altered pharmacological and/or toxicological response. The route of dose can also change the levels of total circulating drug, in particular, dosing by routes other than the oral route (e.g., intravenous, subcutaneous, inhaled) will result in first-pass metabolism being avoided.

Differences in the metabolic route between species are common, e.g., the rat mainly hydroxylates amphetamine leading to conjugated products whereas the rabbit and guinea pig (and man) mainly deaminate amphetamine. Acetylation of aromatic amines occurs in humans but not dogs while glucuronic conjugation is very poor in the cat. A good example of a compound that has the same routes of metabolism in different species but different rates is caffeine, as shown in **Table 3**. Species differences can be

**Figure 6** *p*-Aminosalicylic acid metabolism.

**Table 3** Species differences in caffeine metabolism

Parameter	Man	Monkey	Rat	Rabbit
Total metabolism	322	235	160	137
Theobromine	28	13	15	19
Paraxanthine	193	11	20	42
Theophylline	16	190	20	30

Rates expressed as  $\mu$  moles of product per min per mg protein. Reproduced with permission from Berthou *et al.* (1992) *Xenobiotica* 22: 671–680; © Taylor & Francis Ltd.; <http://www.tandf.co.uk/journals>.

important and usually animals are selected for toxicology studies on the basis of whether their metabolism most closely mimics the expected metabolism in humans.

Genetic differences within species (genetic polymorphism) may result in absences or deficiencies in enzymes, which may predispose individuals to adverse reactions. A genetic deficiency in the P-450 isoenzyme family (lack of CYP2D6) in a proportion of the population is why the antihypertensive debrisoquine is poorly metabolized in certain individuals (Figure 7).

A genetic polymorphism that leads to individuals having differences in their ability to acetylate compounds means that those classed as 'slow-acetylators' can have greater exposures to unconjugated reactive phase I products as has been observed for the anti-tuberculosis drug isoniazid.

The rates and routes of metabolism can vary with age and the lower rates and reduced routes of metabolism usually seen in the young and the old can make them more susceptible to drug action. Differences in hormonal levels, in particular, can lead to differences in metabolism between sexes. Dietary and environmental factors such as the presence of alcohol and cigarette smoke can affect metabolism, as can certain disease conditions, e.g., liver disorders, diabetes. Such conditions can lead to decreased enzyme activity, altered hepatic blood flow, and changes in plasma protein levels which, in turn, can affect circulating 'active' drug levels.

**Drug–drug interactions** Many compounds are able to 'inhibit' metabolizing enzymes, i.e., decrease their activity (cause an increase in steady-state plasma concentrations and a decrease in clearance). Inhibition can take place through the destruction or direct inhibition of the enzyme or the formation of a complex with it. Drug–drug interactions can occur when inhibition of the metabolism of a drug by a co-administered one leads to higher than expected levels of a pharmacologically active moiety. Also, the inhibition of some conjugation reactions can allow

**Figure 7** Distribution and rate of metabolism of debrisoquine in the Caucasian population. (Reproduced with permission from Gibson G and Skett P (1994) *Introduction to Drug Metabolism*, 2nd edn., ch. 4, p. 113; © Nelson Thornes Ltd.)

chemically reactive metabolites to escape detoxification and cause a toxic effect. A well-known example of a drug–drug interaction was the case of the non-sedating antihistamine terfenadine (a substrate for CYP3A4), which when co-administered with the antifungal ketoconazole, a potent inhibitor of CYP3A4, led to higher than expected plasma levels and cardiotoxic side effects. Another example is that of the stomach ulcer drug, cimetidine, which, when co-administered with the anticlotting drug warfarin, inhibited its rate of metabolism and dangerously lengthened blood clotting times.

Many compounds are able to 'induce' metabolizing enzymes, i.e., increase their activity (cause a decrease in steady-state plasma concentrations and an increase in clearance). The induction of metabolizing enzymes results in either an increase in their own metabolism (auto-induction) or that of other drugs (drug–drug interactions). It can reduce the toxicity of the parent molecule but lead to the enhanced formation of a chemically reactive metabolite and thereby overwhelm the detoxification processes. Sometimes, these metabolites can prove to be carcinogenic, e.g., polycyclic aromatic hydrocarbons. However, because enzymes are often induced in animals at higher doses than those used in man, the overall effect may not be clinically significant. On a purely practical level, enzyme induction may mean that it will be difficult to maintain efficacious levels and during regulatory toxicity studies it may not be possible to achieve high enough exposures to see toxicity. A number of CYPs are now usually monitored to assess the inductive capacity of test drugs including: CYP1A1, 2C, 2E, and 3A isozymes. For the reasons stated it is better to avoid developing drugs that are potent enzyme inducers, but, nevertheless, many important marketed

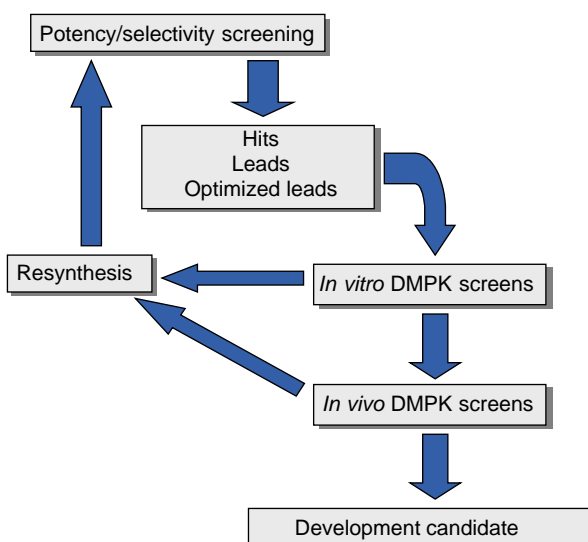

drugs are inducers, e.g., phenytoin, carbamazepine, phenobarbitone.

## Assessment of ADME/PK

ADME/PK has a major role in the research and development of new drugs. The process of drug discovery can be divided into a number of distinct phases: hit screening and lead generation/optimization. The goal of the hit screening phase is to screen compound libraries to find molecules with a specific biological response, usually an *in vitro* potency. At the lead generation/optimization step the main aim is to apply structure activity relationships to improve upon these hits to produce leads that in turn are amenable to further optimization to produce the development candidate. The ADME/PK evaluation of compounds occurs throughout these phases but is particularly useful during lead generation/optimization. A schematic diagram of the discovery process from an ADME/PK perspective is shown in Figure 8.

Many methods are available for investigating key ADME/PK issues. Absorption issues include poor membrane permeability, extensive P-glycoprotein efflux, and poor physicochemical properties. Clearance/metabolism issues include extensive gut metabolism, extensive hepatic metabolism, enzyme induction and inhibition, and transporter-mediated excretion. Distribution issues include extensive protein binding and inadequate tissue penetration. *In silico* (computer-based), *in vitro* (cell-based), and *in vivo* (animal-based) techniques are available for investigating these issues. Structure-based *in silico* models and physicochemical methods allow basic predictions, while *in vitro* models offer a greater level of complexity and most closely mimic the *in vivo* situation. The most promising compounds from an *in vitro* potency and ADME/PK perspective are tested in appropriate *in vivo* pharmacology models. The aim of a typical drug discovery project is to identify a candidate molecule with suitable potency and selectivity against a target, sufficient oral bioavailability, metabolic stability, and duration of action, and minimal developability issues, e.g., potential for drug–drug interactions, ease of synthesis, dose linearity, etc.

Once a compound is selected for development, further studies are performed in animals and man to support the safety assessment and ensure that optimum dosing regimens are selected. Definitive *in vivo* PK and toxicokinetic studies are performed but also more detailed *in vitro* studies, particularly for the assessment of drug–drug interactions. ADME/PK support is continued throughout development (pre-clinical and phases I–IV) and a summary list of the main activities is shown in Table 4.

**Figure 8** Schematic diagram illustrating the typical position of *in vitro* and *in vivo* DMPK screens in the lead generation/optimization phases of the drug discovery process. (Reproduced with permission from Roberts SA (2003): Drug metabolism and pharmacokinetics in drug discovery. *Current Opinion in Drug Discovery and Development* 6(1): 66–80; © Thomson Scientific.)

**Table 4** Main ADME/PK activities performed during drug development

Toxicity testing – monitoring of TK in two nonhuman species
Dose ranging – tolerability over a range of doses
Dose linearity – check of PK proportionality between doses
Definitive PK – single and multiple dose PK
Sex differences – influence of gender on PK
Food interactions – influence of food on PK
Tissue distribution – animals only (usually radiolabeled drug)
Excretion balance – recovery in excreta (usually radiolabeled drug)
Metabolite identification – major routes of metabolism
PK/PD and dose response – determination of clear dose response relationships
Genetic polymorphisms – influence of genetic differences on metabolism
Effect of disease – PK in target population
Dose formulations – PK of final and new formulations
Drug interactions – effect of co-administered compounds on PK

## In Silico Methods

Methods range from those based on molecular structure to those that use complex physiologically-based pharmacokinetic (PBPK) models requiring the input of experimentally determined data. Many physicochemical parameters can be generated automatically from chemical structure including H-bonding, molecular weight, log *P*, p*K*<sub>a</sub>, polar surface area (PSA), and solubility and various software are available to do this. Lipinski's 'rule-of-five' is used by many companies to flag molecules likely to have poor absorption, i.e., compounds that have a molecular weight of

$>500$ , a calculated  $\log P > 5$ , number of H-bond donors  $>5$ , and the number of H-bond acceptors  $>10$ . PSA and rotatable bonds have also proven useful parameters for predicting absorption. A number of more complex models exist, e.g., for plasma protein binding, gastrointestinal absorption, and blood–brain barrier (BBB) penetration, that utilize several physicochemical parameters (calculated and/or experimentally determined). For instance, an algorithm for predicting brain penetration,  $\log BB$  (the ratio of the steady-state concentrations of a compound in the brain and blood), designed using data on a series of brain penetrant compounds, requires PSA and calculated  $\log P$  values as shown in eqn [21]:

$$\log BB = -0.0148\text{PSA} + 0.152C \log P + 0.139 \quad [21]$$

However, one drawback of attempts to model intestinal absorption and BBB penetration is that the effect of transporters is not generally accounted for as the factors that make a compound a substrate or inhibitor are not well understood at present.

Metabolism has proven a difficult event to predict *in silico* but some rule-based expert systems exist and some quantitative structure activity relationship models have been developed. The development of CYP models has been hindered by the lack of three-dimensional crystal structures; however, some homology models have been constructed for key CYP isozymes, e.g., CYP2C9, 2C19, 3A4, and 2D6. In conjunction with homology modeling, site-directed mutagenesis has been shown to help in understanding the relationship between substrate specificity and CYP structures. Important factors for substrate binding and enzyme selectivity include molecular size and shape, number and disposition of hydrogen bond donor/acceptor atoms, and number of aromatic rings in the molecule.

### Physicochemical Methods

Measured physicochemical parameters are useful for the more accurate prediction of events such as drug absorption.  $\log P$  is typically obtained by using potentiometric and spectrophotometric methods to measure the partitioning of a drug between an octanol and a water phase. Solubility is usually measured directly by monitoring achievable drug concentrations in test solutions. For discovery purposes, it is common to measure ‘kinetic’ solubility in which a dimethylsulfoxide solution of the compound is added to aqueous buffer and turbidimetry, nephelometry, and direct ultraviolet methods are used for analysis. However, drug dissolution profiles over time or as a function of pH are generally a better indicator of drug absorption than just inherent

solubility. In addition, a number of artificial permeability assays now exist that attempt to mimic the lipophilic nature of cell membranes and give an indication of absorption potential.

### In Vitro Methods

The most commonly used cell culture model today is the 21-day Caco-2 human colonic cell line derived from a human adenocarcinoma. They can be cultured in special transwell cell culture plates (Figure 9) that enable the investigation of passive diffusion (apical to basolateral side) and active transport (basolateral to apical side). Although the system has its limitations, for many compounds it can give a good indication of likely *in vivo* absorption. An alternative cell culture, which has been shown to correlate well with absorption *in vivo* and permeability in Caco-2 cultures, is the 3-day Madin-Darby canine kidney cell line. Also, the expression of transporter proteins in cell cultures has led to new screens being established for identifying transporter substrates.

A variety of techniques are available for protein binding measurement including equilibrium dialysis, ultrafiltration, spectrofluorometric, and microdialysis methods.

Various cell culture models are available for assessing BBB penetration and although they can give some indication of potential brain penetration, they generally do not form sufficiently tight cell junctions.

A number of *in vitro* hepatic systems are available for assessing metabolism including liver slices, isolated hepatocytes, subcellular fractions (e.g., S9 and microsomes), and purified enzymes. Predictions of *in vivo* clearance can be made using *in vitro* intrinsic clearance ( $Cl_{int}$ ) values derived from liver microsomes or hepatocytes. In addition to methods for assessing enzymic clearance, some exist for investigating drug efflux/uptake in the liver, e.g., isolated

**Figure 9** Schematic diagram of Caco-2 Transwell.

bile cannicular membranes and sandwich-cultured hepatocytes.

Mass spectrometry (MS) is now employed routinely for metabolite elucidation and in particular methods using quadrupole ion traps and time-of-flight liquid chromatography–MS (LC–MS) have proven very useful. Nuclear magnetic resonance (NMR) techniques are also being applied increasingly for more detailed structure elucidation. To aid in structure design, it is also useful to identify the P450 isoforms responsible for metabolism; cDNA-expressed enzymes and selective inhibitors can be used as well as isoform specific anti-P450 antibodies.

CYP inhibition assays include ones that utilize liver microsomes, isolated/cultured hepatocytes, and human cDNA-expressed enzymes. Typically, LC–MS/MS quantification is used for the microsome and hepatocyte methods while fluorimetric assays are used for the human cDNA-expressed enzymes. Typically, a weak inhibitor is defined as having a  $k_i > 20 \mu\text{mol l}^{-1}$ , whereas a potent inhibitor has a  $k_i < 1 \mu\text{mol l}^{-1}$ .

CYP induction assays are available that utilize liver slices, hepatocytes, and cell-based gene reporter constructs. *In vivo*, microsomes can be prepared from the livers of repeat-dosed test animals to examine if any key CYPs have been up-regulated. In discovery, the models utilizing hepatocyte cultures and cell-based gene reporter constructs have proven most useful. A number of analytical methodologies are available for supporting these various approaches including the LC–MS monitoring of probe compounds, mRNA analysis, and ribonuclease protection assays.

In addition to cell-based models, tissue-based models such as the Ussing chamber technique, the everted gut sac approach, and perfused isolated intestinal segments are also used, but only when it is important to understand the absorption processes in more detail. Unlike Caco-2, tissue-based models have the correct physiological levels of transporters and the presence of an apical mucus layer. Also, *in situ* and isolated organ perfusion methods exist for the gut, liver, lungs, kidneys, and brain and can provide data not directly obtainable *in vitro*. The isolated perfused liver is particularly useful since it allows an assessment of first-pass hepatic clearance, the quantitative distribution of metabolites in liver, blood, and bile, the effects of binding to plasma proteins and intracellular sites, and cellular uptake processes.

### In Vivo Methods

Key PK parameters such as bioavailability, plasma elimination half-life, clearance, and volume of

distribution can be generated from PK profiles following oral and intravenous dosing. The efficiency of PK data generation has improved in recent years with the introduction of more sensitive higher throughput methods of analysis. The use of venous cannulated animals and multiple compound (cassette) dosing have contributed to the greater use of *in vivo* PK in drug discovery. Additional information can also be obtained in animals from biliary excretion studies through the cannulation of the common bile duct or gall bladder. Also, transgenic animals lacking or possessing particular gene sequences responsible for important drug metabolizing enzymes and transporters can be used to investigate specific issues. *In vivo* studies provide definitive PK data during development, aid in the design of *in vivo* pharmacology and toxicology studies, and help confirm (validate) the predictivity of *in vitro* methodologies and *in silico* models throughout the drug discovery process.

Methods available for measuring the concentrations of drugs in tissues and body fluids include radioimmunoassay, LC with ultraviolet detection (LC–UV), LC with radioactivity detection, and LC–MS. LC–MS has proven the most attractive method with its good sensitivity and specificity for a wide range of compounds as well as having a minimal sample handling requirement. In addition, MS and NMR techniques are used extensively for metabolite elucidation.

Techniques for quantitative ADME typically employ radiolabeled drugs to look at tissue distribution either in homogenized samples or by whole body autoradiography. Whole body autoradiography involving the location and quantification of radiolabeled material in thin frozen sections of tissue can be particularly useful. Plasma protein binding and metabolism studies also benefit from the use of radiolabeled material.

## Metabolite Isolation and Identification

I P Nnane and X Tao, Temple University, Philadelphia, PA, USA

### Introduction

The study of the metabolism of new chemical entities is very important in selecting drug candidates, and increasingly metabolite isolation and identification studies are performed in the early phase of drug discovery. Drug metabolism studies provide vital information to facilitate the understanding of the pharmacological and toxicological action of drugs and satisfy regulatory requirements. The most common types of drug metabolism assays involve isolation and identification of metabolites generated *in vitro* and *in vivo*. The advent of several new technologies has facilitated the isolation and identification of metabolites, which are often formed in very small quantities in drug metabolism models. For example, the increased use of automation in bioanalysis and the availability of robust mass spectrometers have increased the rate at which data can be generated for elucidation of metabolic pathways. In this article, the current approaches and emerging technologies used for metabolite isolation and identification from various biological matrices are discussed.

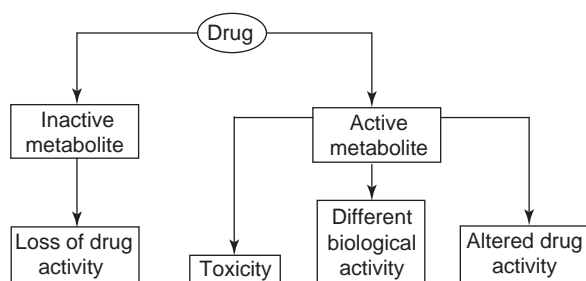

### The Importance of Drug Metabolism Studies

The fate of a drug after administration in animals and humans involves absorption, distribution, metabolism, and excretion (ADME). The body recognizes a

drug as a foreign compound and in most cases the drug is converted to a metabolite through multiple enzymatic pathways. Drug metabolism controls the levels of drugs in the body and may detoxify or activate a drug. In a nutshell, the goals of metabolite isolation and identification include (1) determination of routes of elimination, (2) estimation of rates of metabolic reactions, (3) assessment of metabolic stability, (4) testing of metabolizing enzyme inhibition, (5) structural characterization of formed metabolites, and (6) evaluation of the biological activity of metabolites. Morphine, for example, is converted to morphine-6-glucuronide, which is partially responsible for its pharmacological activity in humans. The various biological outcomes of drug metabolism are shown in **Figure 1**. In recent years, regulatory authorities have also demanded information on metabolite identity and biological activity before new drug applications are approved. In fact, the successful drug candidates must have acceptable ADME, pharmacological, and toxicological profiles. Thus, the role of metabolite isolation and identification studies in selecting better lead compounds with acceptable ADME properties *in vivo* is pivotal in drug discovery and regulatory filing for new drugs.

### Models for Drug Metabolism Studies

Both *in vitro* and *in vivo* models are used to optimize compounds for favorable metabolic properties during drug discovery and development. After administration of a drug to animals and humans, the drug may be transferred from the blood into the liver, the major site of drug metabolism in the body, where it is metabolized or excreted into the biliary system.

**Figure 1** Schematic representation of possible outcomes of drug metabolism.

In many cases, drug metabolism occurs in two stages: Phase I biotransformations, which introduce or unmask functional group(s) in a drug and Phase II biotransformations, which attach endogenous molecules to the parent drug or formed metabolites. Phase I reactions are mainly catalyzed by a family of enzymes known as the cytochrome P450s (CYPs). The common Phase I metabolic reactions include oxidation, reduction, hydrolysis, hydration, dealkylation, and isomerization. Generally, these preparatory reactions make a drug more water-soluble. The metabolites are commonly removed from the body through an excretory route such as the kidneys although other routes may be utilized. Phase II reactions, such as glucuronidation, sulfation, acetylation, amino acid conjugation, and glutathione conjugation, generate highly polar derivatives thereby facilitating drug elimination. Other factors often affect the *in vivo* metabolism of drugs. Hepatic blood flow, for instance, limits the metabolism of some rapidly metabolized compounds *in vivo*.

After administration of a drug to selected animal species, blood, urine, feces, and occasionally bile are collected at predetermined times for metabolite isolation and identification. These whole animal studies are expensive and the metabolic information generated may not be applicable to humans. In addition, the numbers of new drug candidates and the cost of screening them have increased significantly as a result of combinatorial chemistry in recent years. Consequently, *in vitro* drug metabolism methods are increasingly utilized in parallel with *in vivo* models for metabolic stability, metabolite generation, and metabolite profiling because they provide efficient and low-cost approaches in the screening of new drug candidates. The commonly used *in vitro* drug metabolism models include subcellular fractions, hepatocytes, liver slices, and cDNA expressed enzymes. As a result of increased availability and ease of controlling incubation conditions, *in vitro* models are very useful in elucidation of major metabolic pathways, characterization of metabolites, and large-scale synthesis of special metabolites. A major drawback of

*in vitro* models is that they are simplistic and may not accurately predict the metabolic fate of a drug in animals or humans. In addition, *in vitro* enzymatic activities tend to decrease during incubations. Thus, the choice of which *in vitro* model to use depends on several factors including availability and suitability of the model to predict the intrinsic clearance of drugs in humans.

### Subcellular Fractions

Hepatic microsomes remain the simplest and most popular subcellular fractions used to perform metabolic stability studies. Liver microsomal preparations contain numerous CYPs and the flavin-containing monooxygenases that reside in the smooth endoplasmic reticulum. CYP-mediated metabolism of drugs is responsible for many drug interactions. For example, the metabolism of tamoxifen and CYP inhibition by tamoxifen and its major metabolites has been examined in human liver microsomes. Four major metabolites are formed from CYP-mediated biotransformation of tamoxifen in human liver microsomes. Additionally, tamoxifen and its metabolites, *N*-desmethyltamoxifen, 4-hydroxytamoxifen, and 3-hydroxytamoxifen, reversibly inhibited midazolam 1'-hydroxylation, diltiazem *N*-demethylation, and testosterone 6 $\beta$ -hydroxylation with  $K_i$  ranging from 3 to 37  $\mu\text{mol l}^{-1}$  in human liver microsomes. Although liver microsomes are widely used for metabolite profiling, the information obtained from this model is not as complete as that obtained from cellular systems since cellular integrity is lost and some enzymes may require the incorporation of co-factors for optimal activity. Other subcellular fractions such as liver homogenates, which contain both Phase I and II enzymes, are available for *in vitro* drug metabolism studies.

### Isolated Hepatocytes and Liver Slices

The liver is the most commonly used tissue for drug metabolism experiments although other organs, such as the brain, heart, and kidney have also been utilized. Hepatocytes have increasingly become the preferred whole cell *in vitro* system for drug metabolism studies. They provide an environment where enzyme and co-factors are present in normal physiological concentrations and cellular integrity is maintained. Primary hepatocytes are isolated from fresh liver tissue and often possess a broad spectrum of enzyme activities, including reticular, cytosolic, and mitochondrial enzymes. A major disadvantage of primary hepatocytes is that the enzyme activity tends to decrease rapidly with time. However, with the introduction of hepatocyte technologies such as

sandwich culture, gel-immobilized, and cryopreserved hepatocytes, metabolic data are increasingly being generated with long-term hepatocyte cultures.

Liver slices retain intact cell-cell junctions, cellular integrity, and the complete array of drug metabolizing enzymes compared to other *in vitro* systems. Thus, liver slices are attracting increasing attention since complete information on drug metabolism reaction can be obtained in this system.

### Recombinant CYPs

Isolated enzymes responsible for various metabolic pathways are now commercially available due to recent advances in molecular biology. Animal and human CYPs have been expressed from specific cDNA in yeast, bacterial, and mammalian cell lines. These recombinant enzymes are very useful tools for metabolite generation and isolation. The expression of CYPs has been extensively studied since they metabolize a wide variety of drugs. Recombinant human CYPs provide a consistent source of single CYP isoforms, allow incubation conditions to be readily controlled, generally exhibit similar kinetic profiles as demonstrated in human liver microsomes, and permit identification of specific enzymes involved in biotransformations. The metabolism of all-*trans*-retinoic acid (RA) to its 4-hydroxy derivative, for example, has been examined in cDNA-expression systems (Figure 2). These studies have identified CYP26A as the principal isoform that mediates the 4-hydroxylation of RA in animals. It is acknowledged that systems containing cDNA-expressed enzymes are artificial because the enzyme is not present in its native environment, is often over-expressed, and the activity of the expressed enzyme may differ from that of the native one. In order to overcome this limitation, well-characterized cDNA-expressed enzymes must be used and sufficient attempt made to

relate *in vitro* data to the level and activity of the enzyme in the native tissue.

### Metabolite Isolation

The sample types encountered in drug metabolism studies consist of enzymes, other endogenous compounds, and varying concentrations of target drugs and their metabolites. In many instances, the analysis of metabolites in these biological matrices requires a sample preparation step before the samples are introduced into an analytical instrument such as high-performance liquid chromatography (HPLC). The primary purpose of sample preparation protocols is sample purification, isolation, and concentration of the analytes prior to chromatographic analysis and structure elucidation of the drugs and their metabolites.

The overall efficiency of the analytical procedure and the accuracy of the results obtained are influenced by the effectiveness of the sample preparation method. Several technologies are used for metabolite isolation from various biological matrices during *in vitro* and *in vivo* drug metabolism studies. Appropriate isolation procedures account for the stability of the metabolites and allow for efficient separation of the metabolites from the matrix resulting in relatively clean fractions that make metabolite identification easier. The common techniques used for metabolite separation and isolation such as protein precipitation, solvent extraction, and solid-phase extraction (SPE) have been discussed at length previously. Isolation of metabolites that are bound to proteins may also be accomplished, although the commonly used procedures may change the structure of the metabolites. Protein-precipitating agents (e.g., trichloroacetic acid, acetonitrile, or methanol) are often used as the first step for denaturing the proteins that are present in the biological samples in order to get rid of interfering macromolecules and in the process liberate the bound drug and metabolites. Additional sample cleanup by solvent or SPE is usually conducted to isolate the unbound metabolites before analysis. The common methods for sample preparation are increasingly being transferred to automated platforms in order to support large-scale metabolite isolation studies. A significant degree of changes toward miniaturization and automation have been made in SPE in order to minimize the number of steps involved in sample preparation procedures, reduce potential sources of error and the time required to conduct routine assays, and generally to make the processes less labor-intensive. The use of multiwell plates and column-switching methodologies for SPE are making a major impact in sample preparation during the drug discovery phase.

**Figure 2** Metabolic pathway of all-*trans*-retinoic acid (RA) to its hydroxy- and oxo-derivatives by cytochrome P450 (CYPs).

SPE is carried out with many sorbent phases (e.g., C8, C18, silica, CN) in cartridge, disc, and 96-well plate formats for online sample preparation. For example, an online extraction column containing C18 has reportedly been used to study the CYP3A4-mediated hydroxylation of testosterone in liver microsomes. The separation of testosterone and its metabolites from microsomal proteins was based on reversed-phase partitioning and size exclusion; the C18 groups retained the drug and metabolite molecules in the pores in the inner surface of the column while the extraction mobile phase washed away the protein molecules. After the proteins had been washed away, the valve was switched to allow the elution mobile phase to go through the extraction column in order to elute the retained drug and metabolites onto the analytical column for chromatographic separation and analysis. This online sample preparation approach coupled to automated analysis using an autosampler is flexible to handle different assays.

## Chromatographic Methods for Metabolite Separation and Isolation

Chromatographic techniques still make up the vast majority of methods for separation, isolation, and purification of drugs and their metabolites from biological samples in drug metabolism studies. Although separate chromatographic methods are still required for each drug and its metabolites, significant improvements in the limits of detection of the assays have been realized, especially for hyphenated methods such as HPLC–mass spectrometry (MS) (*vide infra*). In addition, major improvements in software for controlling the analytical instruments and for data acquisition and management have resulted in significant reductions in the time required to conduct bioanalysis. The software is useful for accurate recording of the retention times, intensity of the chromatographic peaks, and for obtaining the spectra for analytes of interest, thereby allowing the bioanalyst sufficient time for data interpretation. These methods will continue to have a major impact in metabolite isolation and identification in the future.

### Metabolite Identification

The elucidation of metabolite structure is usually conducted in several steps that involve isolation of metabolites from appropriate biological matrices, metabolite detection, and quantification followed by structural characterization and comparison to synthesized standards. This approach is based on the

premise that it is possible to predict the common metabolic pathways such as oxidation and glucuronidation of new drugs and therefore a targeted search of potential metabolites is conducted. After metabolite isolation and separation is accomplished, specialized technologies are required for metabolite identification. The standard spectroscopic techniques, such as ultraviolet (UV), MS, infrared spectroscopy, and nuclear magnetic resonance (NMR) may be used offline after metabolite isolation or linked with gas or liquid chromatographic methods for metabolite identification. The use of radiolabeled and stable isotopes has also facilitated metabolite isolation and detection for some drug candidates, which lack strong chromophores or fluorophores in their structure. The isolation and identification of metabolites is tedious, time consuming, and requires careful data interpretation in order to unravel the chemical structures. In order to overcome this drawback and address the increasing number of compounds encountered during metabolic stability studies, automated hyphenated techniques utilizing chromatography with UV, fluorescence, radiometric, NMR, and MS detectors, and improved software for data acquisition are now in routine use. Of all the instruments available for metabolite identification, MS has undergone significant innovations and emerged as an ideal technique for the characterization of structurally diverse metabolites. Our discussion will now focus on innovations in some MS instruments that have impacted metabolite identification in recent years.

## Mass Spectrometry

New developments in MS technologies are useful in distinguishing minor differences in the mass ion spectra for different metabolites. The commonly used ion separation analyzers are quadrupole MS, ion-trap MS, time-of-flight (TOF) MS, and Tandem MS. The common modes of ionization in MS include (1) electron impact ionization (EI), (2) chemical ionization (CI), and (3) atmospheric pressure ionization (API). A detailed discussion of all the available MS instruments and their modes of operation is beyond the scope of this article. Briefly, the quadrupole MS is the most frequently used mass analyzer for small molecules and can scan a mass range of 80–700  $m/z$  in  $\sim 0.5$  s. Additionally, it can detect both positive and negative ions and perform product ion scanning, precursor ion scanning, neutral loss scanning, and selected reaction monitoring for high sensitivity. Ion-trap mass analyzers such as three-dimensional quadrupole ion-trap MS that have the potential to define the sites of metabolism more clearly are also

available. Modern ion-trap MS operates by storing ions in a trap and manipulating the ions using electric fields in a series of carefully timed events. This approach provides some unique capabilities to perform a variety of tandem MS experiments with very high sensitivity and resolution that are helpful in determining the structure of a metabolite.

TOF MS measures the mass-dependent time that it takes for ions of different masses to move from the ion source to the detector. For this to work well, the time at which the ions leave the ion source must be well defined. Therefore, ions are either formed by a pulsed ionization method or various kinds of rapid electric field switching may be used as a 'gate' to release the ions from the ion source in a very short time interval. TOF MS has the capability of acquiring spectra every 10–100  $\mu$ s and can efficiently define chromatographic peaks from very fast separations. Additionally, TOF MS is very sensitive with great mass accuracy.

Recent innovations in coupling MS instruments to chromatographic systems have made it possible to systematically isolate and elucidate the structures of a wide variety of metabolites. MS instruments can be readily coupled to GC; the gaseous mobile phases and volatile analytes make development of the interface between GC and MS relatively easy. GC–MS systems are very versatile in separating mixtures into their individual components, identifying structure, and providing quantitative and qualitative information for drugs and their metabolites. In contrast, the HPLC solvents are not an ideal interface for MS. The compounds in the liquid phase eluting from the HPLC system are at atmospheric pressure, while MS is only open to ions in a gas phase at high vacuum. Therefore, a suitable interface between HPLC and MS must have the capability to remove the solvents and ionize the analytes.

### Atmospheric Pressure Ionization Mass Spectrometry

The advent of API MS has revolutionized the analysis of drugs and metabolites in biological samples. The API source provides an ideal interface to link HPLC to MS utilizing two ionization methods: electrospray ionization (ESI), which ionizes the molecules in the mobile phase, before the ions arrive in the gas phase, and atmospheric pressure chemical ionization (APCI), which ionizes the molecules after they are already in the gas phase. In APCI mode, both solvent and solutes are rapidly evaporated by heat. After evaporation of neutral species, ions are formed in a gas phase at atmospheric pressure. All species in the gas phase undergo

significant collision with surrounding gases to form ions of sample molecules. APCI is a very efficient mode of ionization for compounds with high proton affinity and it is applicable for ionizable and polar molecules with molecular weight range of less than 2000  $m/z$ . The APCI MS using a quadrupole analyzer is a relatively small and low-cost system, offers good reproducibility, and has wide application in hyphenated systems such as HPLC–MS, GC–MS, and MS–MS systems. HPLC–APCI MS is suitable for identification of a wide range of metabolites and assay sensitivity can reach the femtomole levels. Recently, we developed an HPLC–MS for the simultaneous determination of all-*trans*-RA and its polar metabolites, 4-hydroxy-RA and 4-oxo-RA, in human liver microsomes (Figure 2). The method of detection was carried out using positive ion APCI and selected ion monitoring of the ions  $m/z$  299,  $m/z$  301, and  $m/z$  315 for quantitative analysis. The ion  $m/z$  299 represented the loss of the hydroxyl group from 4-hydroxy-RA, while the ions  $m/z$  301 and  $m/z$  315 represented the protonated RA and 4-oxo-RA molecules, respectively. The limit of quantification was determined to be in the picomole range with excellent accuracy and precision.

### Tandem Mass Spectrometry

A combination of different types of MS, with different ionization techniques, is also very valuable in identifying unknown metabolites. Controlled fragmentation, through tandem MS (also known as MS<sup>*n*</sup>, where  $10 \geq n \geq 2$ ) involving multiple stages of analysis with serially linked MS instruments, is useful for structural elucidation of novel drugs and metabolites. Tandem MS covers a variety of scanning methods and usually contains ion isolation and fragmentation stages in the same instrument. In the MS/MS mode, a first mass spectrometer (e.g., quadrupole MS) is tuned to allow only the metabolite ion of interest through based on its  $m/z$  ratio. The isolated ion is then passed into a collision cell where an inert gas such as argon is used to fragment the metabolite and the resulting ions are swept into a second mass spectrometer (e.g., ion-trap MS) for separation and detection. During MS<sup>*n*</sup> analysis, a series of fragment ion masses, which correspond to part of an unknown metabolite, can be searched sequentially, permitting the identification of different metabolites. The tandem MS approach can also be coupled with either GC or HPLC. The selectivity and sensitivity of GC–MS/MS and HPLC–MS/MS are extremely high and the structural information obtained from the technique is extensive. In addition,

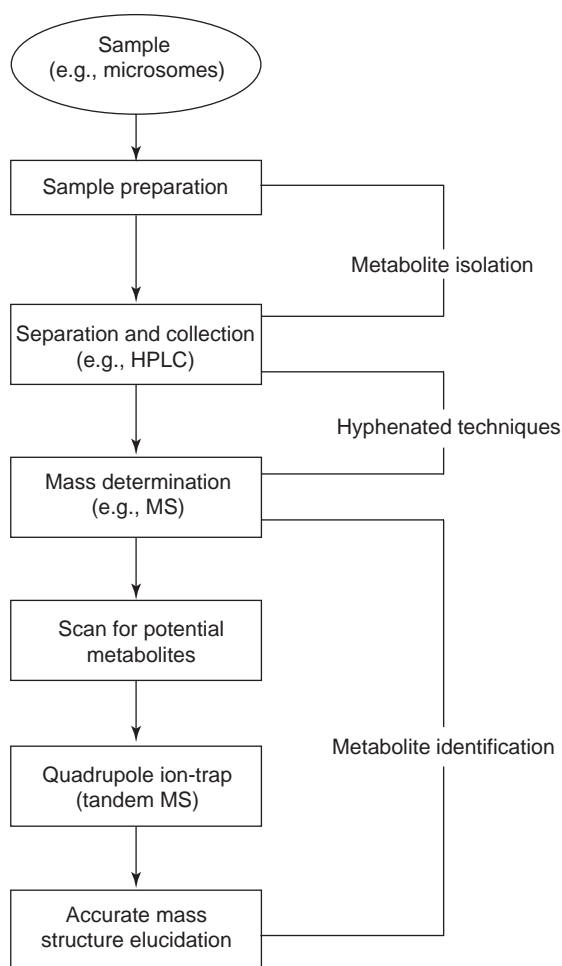

the GC–MS/MS and HPLC–MS/MS technique is robust and may be readily linked to online sample preparation methods for high throughput analysis. Furthermore, combination techniques such as GC–MS/MS and HPLC–MS/MS are the most powerful techniques in drug metabolism studies today by virtue of the fact that they allow the simultaneous separation, purification, quantification, and identification of drug and metabolites with high selectivity and sensitivity as depicted in Figure 3. Notwithstanding, the preferred approach and methods that a bioanalyst chooses depends on availability of a particular analytical instrument, its specificity, accuracy, and the limits of detection of the formed metabolites in a particular matrix.

Interestingly, the increased selectivity of MS instruments has made it possible to circumvent the process of HPLC method development and inject minimally prepared samples directly into the MS

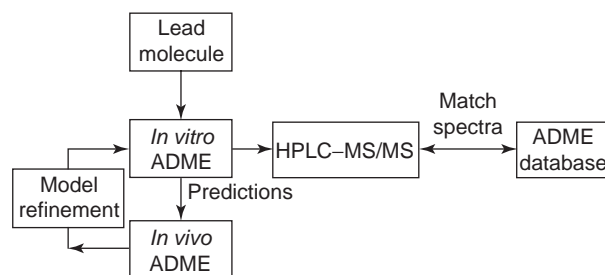

instrument. For example, the high sensitivity of ion-trap MS, by virtue of its capacity to accumulate specific ion populations in the trap, allows direct injection of some biological samples without pretreatment. Furthermore, in flow injection analysis combined with MS (FIA–MS) the sample is injected directly into a stream of mobile phase that is directed into either an ESI or API source, bypassing any HPLC columns. As a result, FIA–MS is the fastest approach for mass detection although it is the least able to determine purity. As improvements in direct-injection MS analysis continue to be made, its contribution to drug metabolism studies will inevitably grow.

## Computational Approaches

Computational approaches are being developed based on past *in vitro* and *in vivo* drug metabolism data in order to increase the efficiency of metabolite profiling and identification even further. In a typical scenario, the ion-trap MS may be used to monitor and characterize the metabolism of lead compounds *in vitro* and *in vivo*. The ions that are detected may be fragmented further by MS<sup>n</sup> methods for additional structural information. The mass spectral data are then transferred to networks for storage and retrieval and metabolite identification accomplished by comparing the fragmentation patterns obtained for specific metabolites to mass spectral databases of potential metabolites as depicted in Figure 4. A promising metabolite database, for providing more realistic predictions of metabolic pathways in various species, is also being developed based on metabolism studies reported in the literature. The importance of computational methods and efficient laboratory information management systems for metabolite identification will become even more apparent as the volume of data generated from drug metabolism studies increases.

## Introduction

The evaluation of absorption, distribution, metabolism, and excretion (ADME) of new chemical entities using *in vitro* and *in vivo* models is a critical step in the discovery and development of potential new drugs. An essential part of drug metabolism studies involves isolation of metabolites from various biological matrices and identification using state-of-the-art technologies. In many cases, biotransformation studies involve detection and measurement of very low concentrations of the formed metabolites in biological matrices for structural characterization and elucidation of novel metabolic pathways. Specialized methods including the use of radioactive and stable isotopes play a key role in metabolite isolation, identification, and profiling. Tracer methods, which involve the use of drugs labeled with radioisotopes (e.g.,  $^{14}\text{C}$  or  $^3\text{H}$ ) or stable isotopes (e.g.,  $^2\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ), are widely used in drug metabolism studies because the tracers can be recognized and quantified by virtue of their decay profiles or mass differences. The application of radioactive and stable isotopes in

drug metabolism studies has a long history. Although stable isotopes such as deuterium were used in drug metabolism studies as early as the 1930s, they were replaced by radiotracer techniques with the advent of liquid scintillation counting. Resurgence in the application of stable isotopes to drug metabolism studies has occurred during the last several decades due to the increasing consideration for human health and improvements in analytical methods, such as high-performance liquid chromatography (HPLC), chemical reaction interface mass spectrometry (CRIMS), and gas chromatography–mass spectrometry (GC–MS). The use of isotopes in conjunction with chromatographic techniques linked to detectors such as ultraviolet, fluorescence, or mass spectrometry (MS) facilitates real-time monitoring of administered drugs and their metabolites in different parts of the body with high resolution, sensitivity, and specificity. In this article, we highlight how current and emerging analytical instrumentation for isotopic studies are used to obtain new insights into the biotransformation of drugs.

## Radioactive versus Stable Isotopes

In isotope-labeled compounds, one or more of the atoms of the molecules are replaced with a detectable quantity of radioactive or stable isotope(s) of the

elements present in the molecules by chemical, enzymatic, or other methods. An important consideration before using isotope-labeled compounds as tracers for obtaining metabolic and pharmacokinetic data is the choice of the label. Briefly, an ideal tracer should have the same physical, chemical, or biological properties of interest as the natural molecule but should also possess some characteristics that will facilitate its detection in the system where the natural molecule is present. In preparing an isotope tracer, it is also important to substitute one or more of the naturally occurring atoms in a specific position in the natural molecule, which is useful for determining the metabolism of the compound, with an isotope atom such that the label does not affect the ADME of the drug under investigation.

Radiolabeled isotopes are frequently used in drug metabolism studies by virtue of the fact that radioactive species do not occur naturally, can be readily traced, and provide a convenient method of measuring very low concentrations of unknown metabolites in complex biological matrices, with very high sensitivity and specificity. The most frequently used radioisotopes in drug metabolism studies are  $\beta$ -emitting nuclides such as carbon-14 ( $^{14}\text{C}$ ) and tritium ( $^3\text{H}$ ). Although it is easier to insert  $^3\text{H}$  into a drug molecule,  $^{14}\text{C}$  is usually preferred because it provides higher activity when inserted at a suitable site in a drug molecule and may offer far more accurate information on the fate of a drug in the body. Radioactive substrates decay by  $\beta$ -emission and the kinetic energy of the emitted particles poses a serious health problem. Other major limitations of using radioisotopes include (1) the environmental concerns of radioactive waste disposal, (2) the exposure to radiation may be too high to permit the use of radiolabeled isotopes for some drugs with relatively long half-lives, (3) the detection of some radiotracers with very short half-lives (Table 1) may be difficult to accomplish, and (4) radioactive isotope studies are not approved in women and children for obvious health concerns.

Stable isotopes offer considerable promise to overcome some of the drawbacks of radioactive isotopes. In stable isotope-labeled drugs, the naturally abundant isotopes of hydrogen, carbon, and nitrogen ( $^1\text{H}$ ,  $^{12}\text{C}$ , and  $^{14}\text{N}$ ), for example, are replaced with the respective rare stable isotopes of these elements ( $^2\text{H}$ ,  $^{13}\text{C}$ , and  $^{15}\text{N}$ ). Although stable isotopes differ from the naturally abundant elements in mass, they do not decay and therefore are not radioactive. The extra mass found in stable isotopes can be exploited to distinguish between chemically identical molecules by precise measurement of their masses for structure determination. In fact, the addition of stable isotopes

**Table 1** Physical properties of some isotopes commonly used in metabolism studies

Element	Stable isotope		Radioactive isotope	
	Mass	Natural abundance (%)	Mass	Half-life
H	1	99.985	3	12.33 years
	2	0.015		
C	12	98.89	11	20 min
	13	1.11	14	5730 years
N	14	99.63	11	500 years
	15	0.37	13	10 min
I	127	100	121	2.12 h
			123	13.27 h
			125	59.4 days
			126	13.11 days
			128	24.99 min
			129	$1.57 \times 10^7$ years

at known concentrations to biological samples before analysis has enabled positive identification and quantification of several drugs and metabolites. Although stable isotopes differ from the natural isotope by one or two atomic mass units, they rarely generate additional toxicities beyond that of the natural molecule itself. Heavy stable isotopes such as  $^{13}\text{C}$ ,  $^{15}\text{N}$ , or  $^{18}\text{O}$ , for example, which differ marginally in mass from the predominant isotopes, do not show any adverse biological effects even at high enrichments. On the other hand, deuterium ( $^2\text{H}$ ), which differs markedly in mass from the predominant hydrogen isotope, may induce serious side effects at high concentrations in body fluids. It has also been shown that there is approximately a 15% difference in the excretion rates between deuterated and non-deuterated norephedrine in humans. In any case, there are several advantages of using stable isotopes over radioactive ones in drug metabolism studies: (1) use of stable isotopes is feasible in pregnant women and children; (2) stable isotopes allow simultaneous and repeated administration of several different tracers through different routes for evaluation of excretory pathways; (3) the substrate content and the isotopic enrichment could be measured simultaneously; (4) the biological specimen can be stored for long periods for subsequent analysis of the stable isotope; and (5) the isotopic effects associated with stable isotopes are smaller compared with radioactive isotopes.

The disadvantages of the use of stable isotope tracers result, to a large extent, from the fact that they also occur naturally, and therefore only changes in the natural background caused by administration of the tracer can be detected. Hence, the sensitivity

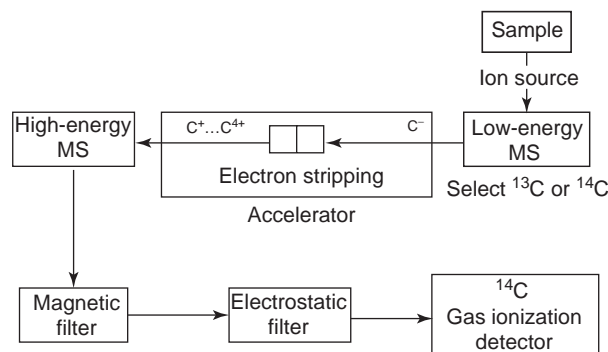

for stable isotopes is usually limited by their relatively high abundance in all natural materials. For example,  $^{13}\text{C}$ -labeled compounds are not distinguishable from the natural carbon compounds when diluted by about five orders of magnitude because  $^{13}\text{C}$  is 1% abundant in nature (Table 1). Since stable isotopes do not emit any radiation, measurements must be made directly on the substances, which in many cases require the isolation of the analyte from complex biological matrices. The measurement of stable isotopes also demands sophisticated analytical techniques and the studies are often quite expensive especially for high enrichment isotopes. Interestingly, new advances in MS have enabled the quantitative detection of stable isotopes with better selectivity, sensitivity, and resolution in drug metabolism studies. It is likely that stable isotopes will continue to play an important role in drug metabolism studies in the foreseeable future as a result of increasing availability of new methods of detection. Ultimately, the choice between radioactive or stable isotopes for drug metabolism studies should take into consideration the cost and safety of the isotopes and the availability of appropriate analytical instruments.

## Measurement of Radioactive Isotopes

In ADME studies, the administered drug and its metabolites must be isolated and characterized in order to obtain a clear picture of the metabolic pathways at play. Frequently, a radiolabeled drug is administered and measurement of radioactivity in the collected biological samples is conducted. Liquid scintillation counting (LSC) or HPLC coupled to a radioactivity detector are commonly used to detect and quantify the radioactivity in the collected tissues and body fluids. The application of LSC and HPLC techniques in drug metabolism studies was discussed in a previous account on this topic. Briefly, the LSC technique is based on decay properties and therefore, is not a particularly efficient way to measure radioisotopes that have long half-lives (Table 1). The counting of the decayed atoms of  $^{14}\text{C}$ , for example, is feasible since its half-life is relatively short (5730 years) although it is time consuming and requires a relatively large sample size. Other radioactive isotopes such as  $^{36}\text{Cl}$  and  $^{129}\text{I}$  have half-lives of up to  $10^7$  years, very slow decay rates, and require a large sample size and incredibly long counting times. Recent innovations in mass spectrometry, for example, accelerator mass spectrometry (AMS), are increasingly being applied to conduct isotope studies because they provide improved efficiency for measurement of radioisotopes.

## Accelerator Mass Spectrometry

AMS has quickly become the preferred method for radioactive isotope measurement because it is much faster and sensitive compared to the traditional methods. The AMS unit consists of several parts, all of which are controlled by a computer (Figure 1). However, a detailed discussion of the architecture and mode of operation of AMS is beyond the scope of this article. Briefly, the AMS procedure usually consists of several steps: a radiolabeled drug is administered to a subject and appropriate samples are collected. For the measurement of  $^{14}\text{C}$ -labeled compounds, for example, the samples are extracted, converted to  $^{14}\text{CO}_2$ , and subsequently to graphite. The AMS method is then used to measure the isotope ratio (e.g.,  $^{14}\text{C}/^{12}\text{C}$ ). AMS is a suitable method of detecting long-lived radioisotopes without regard for their decay products or half-life (Table 1). Since AMS counts individual atoms of radioisotopes, its sensitivity is extremely high and only milligram-sized samples are required. AMS has been reportedly applied to the detection of  $^{14}\text{C}$ -labeled urinary metabolites of the triazine herbicide, atrazine, and the analytical performance of AMS was directly compared to that of LSC. Ten human subjects were given a dermal dose of  $^{14}\text{C}$ -labeled atrazine, urine was collected, and analyzed by both AMS and LSC. AMS provided superior concentration ( $2.2$  versus  $27\text{ fmol ml}^{-1}$ ) and mass ( $5.5$  versus  $54\,000\text{ amol}$ ) detection limits relative to those of LSC in human urine samples. This level of sensitivity will positively impact drug metabolism studies especially during the drug discovery phase. Although AMS requires the use of radioactivity, the radiological dose required is less than  $10\text{ nCi}$  of  $^{14}\text{C}$  labeled drug. This amount of radioactivity is allowed in Phase I ADME studies since there is negligible radiation damage and no serious radioactive waste disposal problems are encountered. A major limitation to the application of

**Figure 1** Schematic representation of the accelerator mass spectrometer.

AMS technology to drug metabolism studies is low instrument availability as a result of its high cost and large size. It should also be pointed out that although several studies with AMS have been carried out with radioisotopes, the potential of this technology for the measurement of stable isotopes has not been fully exploited.

### Online Liquid Chromatography-Accurate Radioisotope Counting

Several analytical techniques such as GC and HPLC have been coupled with AMS and applied efficiently and satisfactorily to drug metabolism studies. However, direct combustion of the GC or HPLC effluents within a microwave-induced plasma chamber prior to AMS analysis is required since no suitable interface is currently available for introducing the HPLC effluent directly into the AMS online. In a recent development, however, an online detection method combining liquid chromatography-accurate radioisotope counting (LC-ARC) with a radioactivity detector and mass spectrometer has been reported. The interface of the LC-ARC system with the mass spectrometer permits effective online radioisotope measurement and acquisition of mass spectrometric data for metabolite isolation and identification. The LC-ARC system has been successfully used for online separation and identification of [ $^3\text{H}$ ]propranolol metabolites with limited sample preparation. Thus, hyphenated techniques involving a combination of LC-ARC with radioactivity detection and MS offer considerable promise as effective tools for metabolite isolation, identification, and profiling.

### Positron Emission Tomography

Whole-body autoradiography (WBA), a resourceful tool for the estimation of the tissue distribution of drugs in animal models of drug metabolism, was described previously. In any event, WBA is increasingly being used for lead optimization and tissue distribution studies in several animal species during early drug discovery. Additionally, lead compounds can be radiolabeled, administered, and whole-body sections imaged quickly to obtain information related to tissue pharmacokinetics, routes of elimination, cytochrome P450-mediated metabolism, and interspecies kinetics. Nowadays, new imaging techniques, such as positron emission tomography (PET), can also be applied to determine the metabolism and pharmacokinetics of labeled drugs *in vivo*. After administration of a labeled drug, PET may be used to measure the distribution of radioactivity in different tissues and obtain information on the metabolic stability of a drug *in vivo* with very high

sensitivity and specificity. PET employs drugs labeled with short-lived positron emitting radionuclides such as  $^{11}\text{C}$ ,  $^{13}\text{N}$ ,  $^{15}\text{O}$ , and  $^{18}\text{F}$ , and by measuring the destruction of radiation using a coincidence technique. A major advantage of PET is that human studies can be performed with the techniques since very low amounts of the radiolabeled drugs have to be administered. In most cases, the radionuclides for PET are usually produced in-house since they are short-lived. Carbon-11 is especially useful because almost every compound in nature contains carbon. Hydrogen, on the other hand, has no radioactive isotope that decays with emission of radiation, which can be detected outside of the human body. In order to circumvent this problem,  $^{18}\text{F}$  is often used as a replacement for a hydrogen atom in a drug, if such a substitution does not alter the properties of the drug in the body. Remarkably, PET is providing new opportunities for lead optimization during drug discovery and for conducting drug metabolism and pharmacokinetic studies *in vivo*.

### Measurement of Stable Isotopes

Mass spectrometric approaches are also very useful for the measurement of stable isotopes in drug metabolism studies. The application of MS to the quantitative measurement of stable isotope has been limited due to the high cost and sophistication of the instruments necessary for stable isotope enrichment studies. Nonetheless, recent improvements in instrument design and performance, as well as computer software for instrument control, data acquisition, and analysis, have increased the sensitivity and reliability of stable isotopic enrichment studies. These new MS instruments, including continuous-flow isotope ratio mass spectrometry (CF-IRMS) and HPLC-chemical reaction interface mass spectrometry (HPLC-CRIMS) are increasingly less expensive, easier to operate, and accessible for mass balance/metabolite identification studies with stable isotopes.

### Continuous Flow-Isotope Ratio Mass Spectrometry

In the CF-IRMS technique, a solid or liquid biological sample is introduced into a high-temperature combustion chamber of an elemental analyzer, where it is converted into a gas. The combustion gases (e.g.,  $^{13}\text{CO}_2$ ,  $\text{N}_2$ ,  $\text{H}_2\text{O}$ ) are carried by a continuous stream of helium, through a cleanup phase, to a gas chromatography-isotope ratio mass spectrometry device. The gases are separated by GC and sent to an ion source where an ion beam is generated for each combustion gas. In the magnetic sector of the mass spectrometer, the beam is split into multiple beams

depending on the molecular weights of the various isotopes contained in the gas. For example, the beam for  $N_2$  is separated into three ion beams and measured at preset masses ( $m/z$  28, 29, and 30) in the collectors. In a biological sample containing a  $^{15}N$  tracer, an increase in masses 29 and 30 above natural abundance will correlate with the concentration of the enriched tracer as atom percent excess. Some efforts have been made to combine HPLC and CF-IRMS for mass balance/metabolite identification studies. However, HPLC effluents must be collected first and then transferred onto CF-IRMS due to the lack of a suitable interface that can accommodate the HPLC effluent directly. In spite of its relatively modest sensitivity ( $\sim 1 \mu g ml^{-1}$ ), the CF-IRMS approach has been successfully applied to analyze  $^{15}N^{13}C_2$ -acetaminophen and to conduct mass balance studies in human samples.

#### HPLC-Chemical Reaction Interface Mass Spectrometry

The CRIMS is increasingly being utilized for the detection and quantification of stable isotope-labeled drugs and metabolites. The universal interface involves a microwave-induced helium plasma that dissociates all analytes to their elemental forms. These species go on to combine with atoms from a reactant gas to form small and stable gaseous molecules that flow into a mass spectrometer. The presence of  $^{13}C$  and  $^{15}N$  is monitored at  $m/z$  45 ( $^{13}CO_2$ ) and  $m/z$  31 ( $^{15}NO$ ), respectively. Since each of these isotopes is naturally abundant, simply detecting these two masses is not sufficient to recognize enriched materials. Nevertheless, if the natural abundance is fixed, the observed signal at the more abundance mass 44 ( $^{12}CO_2$ ) or 30 ( $^{14}NO$ ) is multiplied by the natural abundance of the chemical species being traced, and the product is subtracted from the observed signal for the heavier isotope, the responses from all unenriched material will disappear and only the enriched compound will be traced by the MS. In this approach, the same chemical species are being detected for all analytes; hence, the sensitivity for detection is equal for different analytes. Nowadays, CRIMS can be coupled with HPLC for online analysis of HPLC effluents. The hyphenated instrument, HPLC-CRIMS, constitutes the most powerful separation and detection technique for stable isotope detection in bioanalysis. The HPLC-CRIMS approach has been demonstrated to be effective in the study of the quantitative measurement of a wide range of drug molecules and their metabolites including biologics. Recently, uniformly  $^{13}C,^{15}N$ -labeled rat growth hormone was administered intravenously to rats and blood samples were collected and analyzed using HPLC/CRIMS. The absolute amounts of

$^{13}C,^{15}N$ -labeled rat growth hormone detected ranged from 825 to 66 pmol in a 20  $\mu l$  plasma sample. Interestingly, HPLC-CRIMS has shown excellent agreement to liquid scintillation counting of HPLC fractions.

#### Gas Chromatography-Mass Spectrometry

The application of GC-MS to the study of the metabolism of drugs is a well-developed field. The major advantages of this technique include its ability to rapidly determine many different compounds in complex biological matrices with high sensitivity. A high sample throughput is also realized because extensive sample preparation is often avoided. The present discussion will only highlight the usefulness of GC-MS methods for metabolite profiling of target drugs labeled with stable isotopes. In many cases, the natural and stable-isotope-labeled drug forms differ by one atomic mass unit. These two forms are not usually separated using analytical techniques such as HPLC or GC, since the change in molecular weight by itself does not cause a measurable change in retention times. However, the natural drug form can be distinguished from the stable-isotope-labeled form by GC-MS. In the GC-MS mode, the analytes are not combusted into gases such as  $CO_2$ ,  $N_2$ , and  $H_2O$ , which makes it more suitable for metabolite identification. Measurements of isotopic enrichment by GC-MS typically acquire data by selective ion monitoring (SIM) rather than by a full-scan acquisition. In GC-MS-SIM, ions of the natural and isotope-labeled fragment with specific  $m/z$  values of interest are monitored. The ratio of the tracer to the natural isotope is determined by correlation of the peak area ratio against those obtained for a set of standards of known isotopic enrichment. This technique minimizes potential problems due to label recycling and allows the use of multiple-labeled compounds simultaneously. However, the limited sensitivity of GC-MS-SIM sometimes requires that relatively large amounts of stable-isotope tracers be used.

Isotope dilution gas chromatography-mass spectrometry (ID/GC-MS) is also widely used for the quantitative determination of drugs and their metabolites due to its resolving power, sensitivity, specificity, and accuracy. The use of ID/GC-MS is based on adding a known amount of an isotope-labeled version of the analyte to the sample as an internal standard, equilibrating the labeled analyte with the endogenous analyte, processing the sample, followed by measurement of the ratio of unlabeled to labeled analyte using GC-MS. Assuming complete equilibration with the labeled analyte after spiking, less than complete recovery of the analyte does not affect the measured concentrations. The GC-MS approach using the stable-isotope dilution method has been

reported for the identification of the metabolites of dehydroepiandrosterone formed in human prostate homogenates. A mixture of natural and  $^2\text{H}$ -labeled dehydroepiandrosterone was incubated with human prostate tissue homogenates in the presence of appropriate co-factors. The metabolites were extracted and analyzed by GC–MS. Several metabolites including androst-5-ene-3 $\beta$ ,17 $\beta$ -diol, androst-4-ene-3,17-dione, testosterone, 5 $\alpha$ -dihydrotestosterone, androsterone, and 7 $\alpha$ -hydroxydehydroepiandrosterone were identified based on their chromatographic behavior and mass spectra. GC–MS analyses using stable isotopes are much more difficult and expensive than the usual HPLC and GC procedures. In spite of these limitations, GC–MS approaches using stable isotopes provide powerful tools for investigating drug metabolism in the body and will continue to do so in the near future.

## Introduction

Electrodeposition of metals from solution is a well-established technology. The classical electrogravimetry technique uses the increase in electrode mass associated with exhaustive deposition to provide the quantity of metal species initially present in the solution. Recently, the term has been applied to a technique in which a quartz crystal resonator is used as a gravimetric probe; although not generally coupled with exhaustive deposition, this approach exploits the same processes and has the advantage of *in situ* applicability. In either case, control of conditions can facilitate selective deposition of individual elemental metals from mixtures. The technique can also be used via electrodeposition of compounds of known stoichiometry, notably oxides and halides. This article describes the principles involved, strategies for separation of mixtures, and experimental aspects of the technique.

## Overview

### Definition and Principle

Classical electrogravimetry involves the exhaustive electrolytic deposition of a target solution species onto an electrode as a product of well-defined stoichiometry. The increase in electrode mass then yields the amount of the target species originally present in the analyte. Except where otherwise specified, the text refers to this classical approach.

### Technique Characteristics

Electrogravimetry possesses moderate sensitivity, is a fairly rapid procedure, and has a typical precision of a few parts per thousand for a wide range of metals, present singly or in mixtures. Since the analyte concentration is derived from the quantity measured, via

deposit stoichiometry and relative atomic masses, calibration is not required. The measurand is the mass of deposited material, regardless of the charge required for effecting its deposition. The electron is a reagent that may be used in excess; a 100% current efficiency is not necessary, provided competing reactions do not result in codeposition of other materials or prevent deposition of the required species.

### Historical

The first application of electrogravimetry (described by Luckow and Gibbs in 1864) involved the electrodeposition of copper on platinum at an approximately constant current. The controlled potential method (described by Sand in 1906 and now implemented using a potentiostat) has greater selectivity, vital when determining mixtures of metals. Early applications focused on deposition of elemental metals on Pt cathodes and from 1920 to 1950 procedures were developed for separating and determining numerous metals and alloys. Other chemistries include deposition of lead (as  $\text{PbO}_2$ ) on Pt anodes and of  $\text{Cl}^-$  (as  $\text{AgCl}$ ) on Ag anodes.

### Deposition Strategies

The most common procedure involves the reduction of solution phase metal ions – hydrated or complexed – to elemental metal on the cathode. In the case of anodic deposition of metal as an oxide or halide, the stoichiometry must include any water present.

The simplest experimental configuration employs a two-electrode cell without control of the working electrode potential; this offers no control over the selectivity. If the solution contains more than one depositable species, selectivity–complete deposition of the target metal but no other – is required. This is accomplished in a three-electrode cell via independent control of the working electrode potential, and if necessary augmented by control over the pH and/or complexing agents.

### Relationship to Other Analytical Procedures

Generically, electrodeposition under potential control effects separation of the target species. In

electrogravimetry, subsequent determination is by mass. However, this selectivity can be used prior to determination using any other means. The most obvious example of this, within the same experiment but with the additional constraint of 100% current efficiency, is coulometry. An interesting complement to this is deposition and subsequent amalgamation of metals (Bi, Cd, Cr, Co, Cu, Ga, Ge, Au, In, Ir, Fe, Mg, Mo, Ni, Pd, Pt, Po, Rh, Ru, Ag, Te, Tl, Sn, and Zn) at a mercury cathode, in which the deposited metal may be determined coulometrically or voltammetrically during deposition by anodic stripping voltammetry or by decomposition and solution analysis of the amalgam. Electrodeposition is used for removing other metals from actinides and the separation of U, Np, and Am from higher actinides. Although the standard electrode potentials of the actinides prevent analytically useful electrodeposition, radiochemical samples can be prepared this way.

## Deposition Characteristics

### General Requirements

The primary chemical and physical requirements of the electrodeposited material are purity and adherence, respectively. The ideal deposit is dense, smooth, and stable in the presence of oxygen; this allows it to be washed, dried, and weighed without mechanical loss or reaction with the atmosphere. In the case of elemental metals, 'good' deposits are fine-grained and lustrous. 'Poor' deposits are spongy, powdery or flaky, and less adherent and may contain occlusions of foreign species.

### Deposition of Elemental Metals

A wide range of factors influence the deposit characteristics, and it is commonly necessary to change conditions for successive depositions from mixtures. Typical current densities lie in the range  $10^2$ – $10^4$  A m<sup>-2</sup>. Too high a current density yields a rough, less adherent deposit. If the current exceeds the mass transport limited value for the target ion, hydrogen evolution will occur.

Deposits from complexed metal ions are normally smoother and more adherent than those from uncomplexed metal ions. Complexes that are reduced very easily or with great difficulty tend to give poor deposits; complexes of intermediate stability are optimum. Commonly employed complexing agents are cyanide and ammonia. Large coordinating molecules, such as aromatics, give poor deposits. 'Brighteners' – organic additives used to improve the finish of metal plates – are also used. Some, but not all,

brighteners form metal complexes: for example, glycine, tartaric acid, citric acid, and metaphosphoric acid form complexes with silver and copper and act as brighteners for their electrodeposition, and gelatin improves the smoothness of lead and cadmium deposits. Care must be taken to avoid occlusion of these organics in the metal deposit.

Wherever possible, hydrogen evolution should be avoided: this may be accomplished by control of the pH or cathode potential or by addition of a depolarizer, such as nitrate in the constant current deposition of copper. If the metal ion reduction is accompanied by hydrogen evolution, the metal deposit may be brittle, porous, and nonadherent. The main underlying cause is believed to be the physical effect of bubble evolution rather than the formation and decomposition of metal hydrides.

Stirring the solution has several beneficial effects: it can improve the deposit by replenishing metal ions in the vicinity of the electrode, decrease hydrogen evolution, and increase the electrolysis rate, i.e., decrease analysis time. Temperature effects are less predictable. Temperatures in the range 60–90°C are sometimes used for increasing mass transport and decreasing electrolyte resistance, resulting in denser, more adherent deposits.

### Deposition of Oxides

Anodic deposition of metal oxides or other compounds can result in incorporation of some water. This is accounted for by empirical conversion factors (see Table 2).

## Experimental Aspects

### Solution Composition

Alloys are usually dissolved in acid mixtures; for example hydrochloric acid plus a little nitric acid is used for Cu-, Pb-, Sn-, Zn-, Al-, and Mg-based alloys. Alkaline or acid fusion is used for refractory metals. Complexing agents and then depolarizers are added, and finally the pH is adjusted.

Selective complexation can be used for separating metals of similar deposition potential or for reversing the order of deposition. For example, copper is deposited before cadmium in the presence of cyanide, and after in its absence.

Depolarizers prevent undesirable reactions by providing a facile reaction that prevents the cathode potential from becoming too negative or the anode potential from becoming too positive. Cathodic depolarizers are oxidizing agents that are reduced less readily than the depositing metal ion but more

readily than hydrogen ions and/or other metal ions; an example is nitrate, which is reduced to ammonium. Anodic depolarizers are reducing agents; an example is hydrazine, which is oxidized in an acid medium to nitrogen to prevent chlorine evolution or platinum anode dissolution. Hydroxylamine can act as a cathodic or anodic depolarizer. In determination of lead as the elemental metal, chloride is used to prevent PbO<sub>2</sub> deposition on the anode. When the determination is via PbO<sub>2</sub> deposition on the anode, nitrate is used to prevent elemental lead deposition on a copper-plated cathode.

### Instrumentation and Cell Design

In a classical two-electrode cell the distribution of applied voltage is determined by the reactions at both electrodes, and so there is no independent control of the working electrode potential. Toward the end of electrolysis, the decrease in metal ion concentration allows the cathode potential to become more negative, resulting in codeposition of other metals. For mixtures it is preferable to use a three-electrode cell controlled by a potentiostat such that there is independent control of the working electrode potential with respect to a reference electrode passing no current. The cell resistance is minimized by large area electrodes, high salt concentrations, and (where required) high diaphragm porosity. The electrolysis time is reduced by maximizing the ratio of the electrode area to the cell volume (*V*) and by stirring to minimize the diffusion layer thickness ( $\delta$ ).

### Electrodes

Concentric cylindrical gauze electrodes ensure uniform potential and current distributions. When a reference electrode is employed – historically calomel or mercury/mercury sulfate, more recently (for occupational health reasons) using silver-based couples and occasionally a wire of the metal to be plated – placement of the tip of the salt bridge close to the working electrode minimizes the ohmic potential drop.

The most commonly used working electrode material is platinum, sometimes alloyed with a few per cent of iridium. Two difficulties can arise. First, in chloride media, the Pt anode may dissolve and codeposit with the intended metal on the cathode; platinum dissolution can be suppressed using a depolarizer such as hydrazine sulfate. Second, electrode cleaning is difficult when the deposited metal alloys with platinum. This arises with Bi, Cd, Ga, Hg, Pb, Sn, and Zn but can be prevented by precoating Pt with Cu or Ag.

Other solid electrodes include tantalum and silver (for copper) and nickel (for zinc). Silver anodes prevent evolution of oxygen (which could be reduced at the cathode), and silver cathodes prevent evolution of hydrogen, with associated local pH changes. Addition of chloride allows the anode reaction (eqn. [1])

to proceed at an approximately fixed potential, facilitating controlled potential deposition at the cathode in a two-electrode cell. Silver electrodes cannot be used in complexing media, for example, a cyanide solution or chloride solution sufficiently concentrated to form AgCl<sub>2</sub><sup>−</sup>. One can use a cathode of the metal to be deposited (with a Pt stem for preventing corrosion at the solution/air interface) or indeed any metal for which the deposition potential is more positive than for the metals in solution, provided one uses potential control and is alert to variations in deposition potential with complexing agents.

Before each determination, removal of previous deposits is essential. Anodic dissolution or chemical stripping is used.

A mercury cathode has the advantage of a very large overpotential for hydrogen evolution. The deposited (and amalgamated) metals are determined gravimetrically by distillation of the mercury. In dilute sulfuric acid, the mercury cathode can be used for depositing Fe, Cr, Zn, Cd, Ga, Ge, Cu, Sn, Mo, Pb, Bi, Ag, Au, the Pt metals (except Ru and Os), As, Se, Te, Tl, Re, and Hg. It can only partially deposit Mn. Al, Zr, Ti, P, V, U, Mg, and the alkaline and rare earth metals are left in solution. A hybrid approach is the Paweck electrode, an amalgamated brass gauze used for deposition of Ni, Co, Cd, and Zn.

### Gravimetric Measurement

The requirement is to avoid loss of deposited material. This is accomplished by removal of the electrode from the solution without breaking the circuit, with concomitant washing. With base metals, even prompt washing results in a slight (of the order of a milligram) loss of metal through air oxidation. The electrode is then dried (commonly assisted by washing with a volatile water-miscible organic solvent), heated (110°C for 2–3 min), air-cooled, and weighed.

### Microdeterminations

By using the electrode as the counterpoise of a balance, one can achieve 0.1% accuracy with 1–10 mg metal samples. The difficulties of using a three-electrode cell with small samples can be overcome by using a two-electrode cell with a large counterelectrode whose potential is maintained approximately

constant using a depolarizer. Small-scale separations of Cu from Pb, Sn, Ni, Zn, and Al (for analyses of brass, bronze, and gunmetal), of Bi and Pb, and of metals in solders have been described. Anodic deposition of Pb (as PbO<sub>2</sub>) can also be performed on a small scale. Extension of the conventional technique to submicroquantities presents difficulties associated with submonolayer deposits; the electrochemical quartz crystal microbalance (see below) can accurately quantify such small amounts of material.

## Separation Strategies

Most analytes contain more than one depositable metal, and so a strategy is required for selective or sequential deposition of individual metals; opportunities for this are now described.

### Thermodynamically Based Separation Strategies

Consider separation of metal ions of oxidation state  $z$ , deposited cathodically as the element. The final concentration of metal ions in solution,  $C_{\text{final}}$ , following exhaustive electrolysis of a solution of initial concentration  $C_{\text{initial}}$  at potential  $E_c$  is given by

$$E_c - E_{\text{dep}} = (2.303RT/zF) \log(C_{\text{final}}/C_{\text{initial}}) \quad [2]$$

where  $E_{\text{dep}}$  is the potential for the onset of deposition and the factor  $2.303RT/F$  is equal to 0.059 V at a temperature ( $T$ ) of 25°C. 'Quantitative' deposition requires  $(C_{\text{final}}/C_{\text{initial}}) < 10^{-3}$ , corresponding to  $(E_c - E_{\text{dep}}) < -(0.177/z) \text{ V}$ . Thus, metals with  $E_{\text{dep}}$  values separated by greater than  $0.177/z \text{ V}$  can be separated and determined by alternate deposition and weighing of the electrode. If the required value of  $E_c$  is more negative than  $E_{\text{dep}}$  for another metal, manipulating the potential alone cannot provide separation.

Controlled potential electrogravimetry, using a potentiostat, is commonly used. The applied cell potential,  $E_{\text{appl}}$ , is distributed between the equilibrium anode and cathode potentials ( $E_a$  and  $E_c$ ), the anodic and cathodic overpotentials ( $\eta_a$  and  $\eta_c$ ) and the solution ohmic drop ( $iR$ ):

$$E_{\text{appl}} = E_a + \eta_a - E_c + \eta_c + iR \quad [3]$$

In a three-electrode system, the anode contributions and  $iR$  drop are instrumentally removed. Usually  $\eta_c$  is negligible, and when the current tends to zero (at the end of deposition)  $\eta_c$  tends to zero. Thus, thermodynamic factors provide selectivity via the cathode potential.

When  $E_a$  and  $\eta_a$  remain constant, use of a constant  $E_{\text{appl}}$  approaches the controlled potential method.

This condition is met in a method called internal electrolysis (or spontaneous electrogravimetric analysis), first described by Ullgren in 1868, in which electrolysis occurs by spontaneous discharge of a galvanic cell. To illustrate the principle, consider two half-cells, comprising a zinc rod in a zinc sulfate solution and a copper rod in a copper sulfate solution. At open circuit, 25°C, the reversible cell potential is related to the two standard electrode potentials ( $E^0$ ):

$$E = E_{\text{Zn}}^0 + E_{\text{Cu}}^0 - (0.059/2) \log\{[\text{Zn}^{2+}]/[\text{Cu}^{2+}]\} \quad [4]$$

On connection of the two electrodes, the cell emf drives a short circuit current ( $i$ ) through the cell resistance ( $R$ ), according to

$$E = iR = E_{\text{Zn}}^0 + E_{\text{Cu}}^0 - (0.059/2) \log\{[\text{Zn}^{2+}]_0/[\text{Cu}^{2+}]_0\} \quad [5]$$

where the concentrations now refer to surface values. This is a displacement reaction but with separated half-cells, and so the metal deposits adherently on a stable (not dissolving) surface.

When the deposition potentials are so close that potential control alone is insufficient for effecting separation of the mixtures, it is common to manipulate the deposition potentials using complexing reagents. Complexed metal ions are normally reduced at more negative potentials than are the free ions. Exceptions, for kinetic reasons, are nickel/pyridine and  $\text{SnCl}_4^{2-}$  complexes. Complexation can also improve the deposit quality; for example, silver deposition is excellent from cyanide (as  $\text{Ag}(\text{CN})_2^-$ ), and copper yields much better deposits from pH 4–6 tartrate than from nitric or hydrochloric acids. The stability of many complexes is pH-dependent, and so combined complexation and pH control is used to separate multicomponent mixtures.

Since the pH defines the potential of hydrogen evolution, its variation may be used to extend negatively the potential window for metal ion discharge. One may also use hydrogen evolution for depolarizing or for preventing deposition of less noble metals, subject to the deleterious effects on the quality of the metal deposit (see above).

### Kinetically Based Separation Strategies

The primary exploitation of kinetics for effecting separation relates to hydrogen evolution, the kinetics of which varies significantly with the (metal) electrode material. Slow hydrogen evolution allows copper to be deposited from acid solutions and is the reason why such a wide range of metal ions can be reduced at mercury.

Kinetic separation of metals from each other is less common. A notable exception is the electrogravimetric determination of copper/bismuth mixtures. This relies on bismuth deposition (pH 5.2–6.0,  $-0.30$  V), being extremely slow on platinum or copper-plated platinum but rapid at a bismuth-plated cathode.

## Monitoring the Deposition Process

In controlled potential electrolysis under convective/diffusional control, the reactant concentration decays exponentially with time with an effective rate constant ( $k$  ( $s^{-1}$ )) given by

$$k = DA/V\delta \quad [6]$$

where  $D$  is the diffusion coefficient. The progress can be monitored via the current decay toward zero, at which point the extent of deposition is thermodynamically determined according to eqn [2]. Any  $iR$  drop in solution may extend the electrolysis time by failing to maintain a diffusion-limited current regime. Note that the rate of constant current deposition is subject to similar constraints since any current beyond the diffusionaly limited value will effect a different, possibly undesirable, reaction.

In internal electrolysis, since the cell emf is distributed across the cell as the  $iR$  drop, the deposition rate is inversely proportional to  $R$ : the maximal deposition rate is thus achieved by minimizing  $R$ . The progress of the reaction can be monitored via the cathode potential or current, although variation of  $R$  during the electrolysis distorts the simple exponential decay of the current. The determination itself can be based on spontaneous current measurement during internal electrolysis, although this is not normal practice. For example, determination of cyanide or fluoride in potable water can be based on empirical correlation of current and concentration.

## Applications and Separations

### Classification of Species

Conditions under which common elemental metals can be electrodeposited are shown in **Table 1**. The significance of the groupings is that metals from different groups can generally be separated using potential control alone: successive deposition and weighing sequences allow determination of such mixtures. Separation of metals within a group normally requires an additional control variable, usually

**Table 1** Grouping of metals deposited in the elemental state

Group	Metal	Solution requirement(s)	Comments
Precious metals group	Au	Acid or cyanide	Cyanide allows Au separation In halide media less Hg(II): require greater deposition potential In nitrate, tendency for oxide deposition on anode
	Pt	Acid (not cyanide)	
	Hg	HNO <sub>3</sub> , HCl, or NH <sub>3</sub>	
	Ag	Acid nitrate or citrate; neutral cyanide; ammonia	
Copper group	Cu	Acid sulfate, nitrate, or chloride; alkaline cyanide; ammonia	Cu <sub>2</sub> O formation at high pH
	Bi	HNO <sub>3</sub> , nitrate, chloride, sulfate, oxalate, tartrate	
	Sb	Hot HCl, require Sb(III) state	
	As	As(III) state	
Lead group	Pb	Chloride or tartrate	Alloys with Pt; can also be deposited as oxide on anode
	Sn	HCl	
Zinc group	Ni	Ammonia, oxalate	Redissolves in dilute acids; amalgamated brass cathodes useful (As Ni) (As Ni) (As Ni); alloys with Pt
	Co	Ammonia, oxalate	
	Cd	Alkaline, neutral, or acid media	
	Zn	Acid citrate (controlled pH; not strong acid)	
Mercury cathode group	As, Cr, Ga, Ge, In, Ir, Fe, Mo, Re, Se, Te, Tl	Alkaline media prevents H <sub>2</sub> evolution; complexing agents prevent hydroxide formation	High overpotential prevents H <sub>2</sub> evolution

**Table 2** Species determined as nonelemental electrodeposits

<i>Solution species</i>	<i>Deposited as</i>	<i>Anode</i>	<i>Required conditions</i>	<i>Conversion factor</i>
Pb <sup>2+</sup>	PbO <sub>2</sub>	Pt	Strong HNO <sub>3</sub>	0.8660–0.8605 <sup>a</sup>
Tl <sup>+</sup>	Tl <sub>2</sub> O <sub>3</sub>	Pt	Nitrate/ammonia (Mn, Pb, and Bi interfere)	0.895
Mn <sup>2+</sup>	MnO <sub>2</sub>	Pt	HCOOH/HCOONa	
Co <sup>2+</sup>	Co <sub>2</sub> O <sub>3</sub>	Ag	Acetate buffer	0.710
Br <sup>−</sup> , Cl <sup>−</sup>	AgX	Ag		

<sup>a</sup>Theoretical value: 0.8660.**Table 3** Deposition of metals by internal electrolysis

<i>Metal</i>	<i>Noninterfering metals</i>	<i>Solution</i>	<i>Anode half-cell</i>
Ag	Pb, Cu, Bi	HNO <sub>3</sub>	Cu/Cu(NO <sub>3</sub> ) <sub>2</sub>
Bi	—	HNO <sub>3</sub>	Zn/ZnCl <sub>2</sub>
Cd	Zn	Acetate/NH <sub>4</sub> Cl/N <sub>2</sub> H <sub>4</sub>	Zn/ZnCl <sub>2</sub>
Cu	Ni, Zn	HNO <sub>3</sub>	Zn/ZnCl <sub>2</sub>
Hg	Cu, Zn	H <sub>2</sub> SO <sub>4</sub>	Cu/CuSO <sub>4</sub>
Ni	—	NH <sub>3</sub> /NH <sub>4</sub> Cl/SO <sub>4</sub> <sup>2−</sup>	Zn/ZnCl <sub>2</sub>
Pb	Zn	HCl + 0.1% gelatin; acetate	Zn/Zn(NO <sub>3</sub> ) <sub>2</sub>
Zn	—	Acetate	Mg/NH <sub>4</sub> Cl, HCl

complexation and/or pH. Deposition of the more electronegative elements on a mercury cathode has the (surmountable) complication of mercury loss in transfer, as droplets or by volatilization.

An alternative to cathodic deposition of the elemental metal is anodic deposition of a higher oxide (Table 2). For lead, thallium, manganese, and cobalt, this allows separation from the vast majority of metals. This concept can be extended to determination of bromide and chloride, as the respective insoluble silver halides.

Where the metal can exist in two stable valence states in solution, there is a problem associated with redox cycling between the two electrodes. For example, in concentrated chloride media, reduction of Cu<sup>2+</sup> at the cathode generates CuCl<sub>3</sub><sup>−</sup>, which migrates to the anode and is oxidized back to Cu<sup>2+</sup>, and so Cu<sup>0</sup> is not deposited. In this case, the problem is avoided by keeping the chloride concentration low. An analogous problem can arise with Fe<sup>3+</sup>/Fe<sup>2+</sup> in tartrate media. Even if the cycled metal is not the object of deposition, the decrease in current efficiency can prevent successful analysis.

### Case Studies

Electrodepositions from solutions containing only one depositable metal ion are straightforward. Separations of two-component mixtures also present few problems. Examples include the separations of silver from copper (at −0.24 V in ammoniacal me-

dia), of cadmium from zinc (at −0.80 V in pH 4 acetate media), and of nickel from iron (at −1.10 V in an ammoniacal tartrate medium containing sodium sulfite). For more complex mixtures, the interplay of potential, deposited material, complexation, and pH one must use are illustrated by three case studies. Generally, one must retain close control of the pH in separations from citrate or tartrate media and be aware of the presence of one metal influencing the deposition of another, illustrated by the inhibition by aluminum of copper and bismuth deposition.

None of the examples below involves the internal electrolysis method. This is because, despite its simplicity, it suffers from slow deposition rates. This is less of a disadvantage when the amount of metal to be deposited is small (<50 mg), as in determinations of impurities in more base metals or alloys. Determinations of copper and bismuth in lead–tin alloys or of bismuth in pig-lead fall within this category; other examples are given in Table 3.

*Copper and lead in brasses and bronzes.* Nitric acid treatment of brass leads to chemical separation of tin as SnO<sub>2</sub> · xH<sub>2</sub>O; after filtration and an ignition procedure, the tin can be gravimetrically determined. Thereafter, the analysis is based upon cathodic deposition of Cu and anodic deposition of PbO<sub>2</sub>. If copper alone is to be determined, deposition from a pH 4 tartrate medium with hydrazine as the anodic depolarizer gives separation from most common metals. If lead is also to be determined, one uses a concentrated nitric acid medium, from which PbO<sub>2</sub> is deposited

quantitatively. Copper is not deposited quantitatively under these conditions, and so, following lead deposition, urea is added to lower the nitrate concentration and allow complete Cu deposition. Procedures exist for related samples, such as nickel bronzes and nickel silver (Cu, Ni, and Zn).

*Cu, Bi, Pb, Cd, Zn, and Sn mixtures.* In pH 5.2–5.9 tartrate media, Sn(IV) is complexed. Using gelatin as a brightener and hydrazine as a depolarizer, one can successively deposit and weigh Cu (at  $-0.30$  V), Bi (at  $-0.40$  V), and Pb (at  $-0.60$  V); Pt/Pb alloy formation is prevented by prior deposition of Cu. Addition of ammonia then allows sequential depositions of Cd (at  $-1.20$  V) and Zn (at  $-1.50$  V) since hydrogen evolution occurs at more negative potentials. Addition of HCl decomposes the tin–tartrate complex, allowing tin deposition (at  $-0.65$  V) on a fresh cathode to avoid Zn redissolution. The Pb, Cd, and Zn aspects of this procedure are relevant to the analysis of flue dust from zinc refineries.

*Alloys of Cu, Sb, Pb, and Sn.* This procedure for analysis of bearing metals relies on two successive depositions of pairs of metals. Each (mixed) deposit is dissolved, and then one of the components is selectively deposited (and determined) under different conditions and the other component determined by the difference. First, copper and antimony are codeposited from HCl, with hydrazine as a depolarizer. The (weighed) deposit is dissolved in nitric/hydrofluoric acid, which retains antimony in solution as a fluoride complex, allowing deposition of pure copper (at  $-0.40$  V). Tin and lead are codeposited (at  $-0.70$  V) from the initial residual solution. After redissolution of the (weighed) deposit in nitric/hydrofluoric acids, lead is deposited anodically as  $\text{PbO}_2$ . The Pb and Sn aspect of this procedure is useful for analysis of solders. An analogous procedure allows Ni and Co separation (via  $\text{Co}_2\text{O}_3$ ).

## Recent Developments

Two of the recognized disadvantages of the classical electrogravimetry technique are the need for removal of the electrode from solution for the gravimetric component of the procedure and the practicalities of direct mechanical weighing. The first of these places stringent demands on the deposit characteristics (see above) and makes the procedure slow. The second of these limits the sensitivity of the method. It would clearly be advantageous to have a means of determining the mass of electrodeposited films *in situ*.

In fact, measurements of inertial mass of thin films on solid substrates exposed to a gaseous (or vacuum) environment have long been made using

thickness shear mode (TSM) quartz crystal resonators. The concept is that the resonant frequency of a piezoelectric wafer (here, quartz) sandwiched between two exciting electrodes responds to changes in the acoustic load of the system. For a rigid film typified by the materials, one generally assays using electrogravimetry – this is synonymous with inertial mass. For AT-cut quartz crystal TSM resonators subject to such loading, a change in mass ( $m$  (g)) on an electrode (area  $A$  ( $\text{cm}^2$ )) can be determined from the accompanying resonant frequency change ( $\Delta f$  (Hz)) from its initial value ( $f_0$ ) via the Sauerbrey equation:

$$\Delta f = - \left( \frac{2}{\rho_q v_q} \right) f_0^2 \left( \frac{\Delta m}{A} \right) \quad [7]$$

where  $\rho_q$  and  $v_q$  are the density and shear wave velocity within the quartz respectively. Such a device is referred to as quartz crystal microbalance (QCM).

Immersion in a liquid (as required of an electrochemical experiment) attenuates the propagation of the shear wave, and it was long presumed that this was fatal to *in situ* operation of a QCM. However, it has recently been shown that the crystal continues to oscillate under such conditions. In the electrochemical context, where one uses a conducting solution, the electrochemical QCM (EQCM) technique can be used if only one electrode is exposed to the solution and forms the working electrode in a three-electrode cell. Typical instrumental performance allows frequency (mass) change measurements in response to electrochemically controlled processes on a timescale of less than 1 s. For typical resonators ( $f_0 \approx 5$ – $10$  MHz,  $A \approx 0.2$   $\text{cm}^2$ ), the lower level of measurable frequency changes is of the order of a few Hertz; this corresponds to mass changes of a few nanograms, i.e., a sensitivity of  $\sim 10$  pmol.

Although the EQCM is a relatively new technique and its full analytical potential has not been explored, the above characteristics make it an attractive sensing device. Despite the fact that the principle of mass measurement is different from the classical methodology, measurement of surface mass change using the technique is referred to as electrogravimetry. Interestingly, in addition to the types of system described earlier (metals, oxides, and salts), the *in situ* nature of the technique allows extension to different surface binding chemistries. These may be based on ion exchange, partition into a film, or chemical bonding. In the latter case, this can be anything from coordination chemistry of inorganic analytes to antibody–antigen interactions of biological analytes.

## Introduction: Basic Principles

This article will focus on the use of electron energy loss spectrometry (EELS) in a transmission electron microscope (TEM) or a scanning transmission electron microscope (STEM). In a TEM or STEM, a beam of electrons is accelerated to energies typically between 100 keV and 1 MeV. The beam of electrons is transmitted through a sample that consists of a thin piece of material (typically less than 50 nm thickness). Interaction of the beam with the sample enables the operator to learn something about the sample, such as the chemical elements present, stoichiometry, energy levels, electronic structure, and more.

The EELS technique focuses on the inelastic interaction of the primary beam electrons with the electrons from the sample.

The loss of energy of the primary electrons that is commonly used in EELS is in the range of 0 eV–3 keV. This energy loss is measured by using the dispersive properties of a homogeneous magnetic

field on the charged electrons in an EEL spectrometer. When fast electrons travel through a region of homogeneous magnetic field  $B$  perpendicular to their momentum  $m_e v$ , they are bent in a circular path with radius  $r$  obtained by using the Lorentz force on the particles:

$$r = \frac{\gamma m_e v}{eB} \quad [1]$$

where  $e$  is the charge of the electrons and  $\gamma$  a relativistic correction factor. The radius of the path is thus dependent on the energy of the particle and can be used to discriminate particles with respect to their energy. A so-called EEL spectrum is recorded by counting the primary electrons sorted by energy. A typical spectrum is shown in **Figure 1**. The spectrum is obtained from a thin sample of  $\text{La}_{0.85}\text{Ca}_{0.15}\text{MnO}_3$  and can be divided into several regions that contain information about the sample.

The pronounced peak at 0 eV is labeled as the zero-loss peak. The zero-loss peak contains all primary electrons that did not undergo a noticeable energy loss during the transmission through the sample. The width of this zero-loss peak can mainly be attributed to the effect that the source of primary electrons, the electron gun, has its own intrinsic energy spread. This energy spread is dependent on the type of electron gun but is practically in the order of 0.3–1 eV.

## Introduction: Basic Principles

This article will focus on the use of electron energy loss spectrometry (EELS) in a transmission electron microscope (TEM) or a scanning transmission electron microscope (STEM). In a TEM or STEM, a beam of electrons is accelerated to energies typically between 100 keV and 1 MeV. The beam of electrons is transmitted through a sample that consists of a thin piece of material (typically less than 50 nm thickness). Interaction of the beam with the sample enables the operator to learn something about the sample, such as the chemical elements present, stoichiometry, energy levels, electronic structure, and more.

The EELS technique focuses on the inelastic interaction of the primary beam electrons with the electrons from the sample.

The loss of energy of the primary electrons that is commonly used in EELS is in the range of 0 eV–3 keV. This energy loss is measured by using the dispersive properties of a homogeneous magnetic

field on the charged electrons in an EEL spectrometer. When fast electrons travel through a region of homogeneous magnetic field  $B$  perpendicular to their momentum  $m_e v$ , they are bent in a circular path with radius  $r$  obtained by using the Lorentz force on the particles:

$$r = \frac{\gamma m_e v}{eB} \quad [1]$$

where  $e$  is the charge of the electrons and  $\gamma$  a relativistic correction factor. The radius of the path is thus dependent on the energy of the particle and can be used to discriminate particles with respect to their energy. A so-called EEL spectrum is recorded by counting the primary electrons sorted by energy. A typical spectrum is shown in **Figure 1**. The spectrum is obtained from a thin sample of  $\text{La}_{0.85}\text{Ca}_{0.15}\text{MnO}_3$  and can be divided into several regions that contain information about the sample.

The pronounced peak at 0 eV is labeled as the zero-loss peak. The zero-loss peak contains all primary electrons that did not undergo a noticeable energy loss during the transmission through the sample. The width of this zero-loss peak can mainly be attributed to the effect that the source of primary electrons, the electron gun, has its own intrinsic energy spread. This energy spread is dependent on the type of electron gun but is practically in the order of 0.3–1 eV.

**Figure 1** A typical EEL spectrum from an LCMO ( $\text{La}_{0.85}\text{Ca}_{0.15}\text{MnO}_3$ ) thin film. The spectrum is divided into low-loss and core-loss regions and the zero-loss peak and core excitation edges are labeled. Note the use of a logarithmic intensity scale to cover the wide dynamic range present in a typical EEL spectrum.

Smaller energy spreads are possible by making use of monochromators. The width of the zero-loss peak is the main limiting factor for the energy resolution of the EELS experiment since the experimental spectrum can be regarded as a convolution of an ideal spectrum with the energy distribution of the gun and spectrometer. It is customary to define the energy resolution in EELS experiments as the full-width at half-maximum of the zero-loss peak.

The energy range of  $\sim 0$ – $100$  eV is mostly dominated by the so-called plasmon peaks and is called the low-loss region. Typical for this range is a broad peak at  $E_p$  (typically  $10$ – $30$  eV) that is repeated with decreased intensity at  $2E_p$ ,  $3E_p$ , etc., until the peaks are no longer visible. The origin of these plasmon peaks lies in the excitation of the so-called plasmons (collective oscillations of the valence electrons) by the primary electrons. The position and width of these plasmon peaks are related to the electronic structure of the sample material and can be used to discriminate between different materials.

Apart from collective plasmon excitations, other excitations like valence state excitations and low lying core state excitations are present in the low-loss region and make this region generally difficult to use for chemical quantification. The high probability for excitations in the low-loss range, however, allows the acquisition of high-quality spectra in short exposure times, making it a good region when beam damage is

problematic. A disadvantage is the so-called delocalization effect that intrinsically limits the spatial resolution and can be understood in terms of a classical impact parameter.

Moreover, the dielectric response of the material can be obtained from the low-loss region via a Kramers–Kronig analysis if the EEL spectrum is recorded over a wide energy range. Although the resulting dielectric function has poorer energy resolution than that extracted from, e.g., light absorption spectroscopy, the energy range can be greater covering visible light, ultraviolet, and soft X-ray regions.

The region above  $100$  eV energy loss is generally called the core-loss region. This region is dominated by a smoothly decaying background and element-specific core excitations. These core excitations are caused by the excitation of an atomic core-state of an atom in the sample to an unoccupied higher lying state of the crystal or even to a free electron state. The energy position of these core excitations is determined by the difference in core-state energy and the energy of the first free-state and enables a sensitive discrimination between different elements. Core excitations are generally labeled according to the type of core state that was excited. The naming conventions are given in Table 1 and are used in Figure 1.

The methods of extracting chemical information from a core-loss EEL spectrum are analogous to that in energy-dispersive X-ray (EDX) spectroscopy. The

**Table 1** Naming convention for core excitations depending on core state quantum numbers  $n$ ,  $l$ , and  $j$ 

Label	Core state
K	1s <sub>1/2</sub>

L <sub>3</sub>	2p <sub>3/2</sub>
M <sub>1</sub>	3s <sub>1/2</sub>
M <sub>2</sub>	3p <sub>1/2</sub>
M <sub>3</sub>	3p <sub>3/2</sub>
M <sub>4</sub>	3d <sub>3/2</sub>
M <sub>5</sub>	3d <sub>5/2</sub>

probability of an inelastic core excitation is given by the cross-section  $\sigma_a$ . It relates the number of counts  $I_a$  in a chosen energy range of the core-excitation edge (disregarding the background) to the number of atoms  $N_a$  of a certain element in the interaction volume  $V$  probed by the primary electrons:

$$I_a = I_0 N_a \sigma_a \quad [2]$$

with  $I_0$  the total amount of electron counts in the spectrum.

The volume concentration  $n_a$  is then given by

$$n_a = \frac{I_a}{I_0 \sigma_a V} \quad [3]$$

This enables the operator to determine chemical concentrations from an EEL spectrum if all parameters are known. In general, accurate determination of all these parameters is difficult and mostly the element ratio technique is used to overcome this problem. In the element ratio technique, the ratio of two elements is determined, which cancels out all parameters if both parts of the excitation spectrum are taken at exactly the same experimental conditions:

$$\frac{n_a}{n_b} = \frac{\sigma_b[\Delta E]}{\sigma_a[\Delta E]} \frac{I_a[\Delta E]}{I_b[\Delta E]} = k_{ab}[\Delta E] \frac{I_a[\Delta E]}{I_b[\Delta E]} \quad [4]$$

where  $k_{ab}$  is the so-called  $k$ -factor that can be experimentally determined from calibration samples or can be approximately calculated from physical arguments. It is important to note that these  $k$ -factors are dependent on many parameters (like the energy width  $\Delta E$ ) and they should be considered as microscope dependent. This makes it difficult to publish tabulated  $k$ -factors in contrast to EDX spectroscopy. On the other hand, there is no need for backscattering and absorption corrections that make reliable EDX quantification so difficult.

Moreover, EELS is very sensitive to light elements that are problematic in EDX spectroscopy. This makes EELS an interesting technique to study, for instance, organic materials.

In order to obtain  $I_a$ , the counts in a certain core-excitation edge, one has to get rid of the nonspecific background that is always present in an EEL spectrum. The background is caused by the tails of all lower-lying excitations that add up to a background that is generally approximated by a power-law function  $B(E)$ :

$$B(E) = AE^{-r} \quad [5]$$

where  $A$  and  $r$  are parameters that depend on the experiment and  $E$  the energy loss. The removal of this background is conventionally done by fitting the power-law function in a user-selected region preceding the excitation edge (the so-called fitting region) and then extrapolating it under the excitation edge. After removal of the background, the excitation edge can be integrated over a certain energy range to find the total amount of electrons  $I_a[\Delta E]$  that were scattered by this excitation in the given energy range  $\Delta E$ . These steps are schematically presented in Figure 2 for an MnO sample.

In many cases, the background removed excitation edge is further corrected for the so-called multiple scattering. Multiple scattering is the effect when an electron loses energy to more than one excitation process when interacting with the sample. This leads to a blurring of the experimental spectrum with redistribution of counts to higher energies. Removing this multiple scattering is mostly done by deconvoluting the core-loss spectrum with a low-loss spectrum. This is one of the reasons why in most cases both core-loss and low-loss spectra are recorded during an experiment, taking care that both are recorded under equivalent conditions.

Removal of multiple scattering is especially important if the shape of the excitation edge is to be studied, it removes the thickness-dependent blurring and redistribution and allows for a comparison between the shapes of excitation edges taken from different samples or from different regions in the same sample. The shape of an excitation edge close to the edge onset is related to the electronic structure and can be studied with energy loss near edge structure (ELNES). The shape of the edge at energies slightly above the edge onset can be used to obtain element-specific radial distribution functions with a technique called extended energy loss fine structure (EXELFS). For a detailed description of EXELFS see the textbooks listed in the Further Reading section.

**Figure 2** Extraction of the Mn/O elemental ratio from the spectrum of MnO. Both edges are analyzed within the energy window of the same width (marked in gray) and the characteristic intensity is separated from the extrapolated background. The EELS scattering cross-sections for O and Mn atoms are calculated and integrated over the same windows.

## Technical Details

EEL spectral quantification is very sensitive to the exact microscope setup used by the operator. A successful quantification requires knowledge of at least the following experimental parameters:

- acceleration voltage;
- convergence angle: the angle of the cone that is formed by the electron beam on the sample with respect to the optical axis; and
- collection angle: the angle with respect to the optical axis up to which the transmitted (inelastic) electrons are collected in the spectrometer.

Calibration of these parameters for a specific microscope is essential. The details on what determines these angles are dependent on whether the operator uses a TEM or STEM setup and on the type of spectrometer that is used. The details are treated at length in several of introductory textbooks on EELS mentioned in the Further Reading section.

## Spot Analysis

The simplest operation mode in EELS is focusing the incident electron beam at the place of interest and analyzing the spectral distribution of the transmitted beam. The probe size can be as small as 1 nm and can even be reduced down to atomic sizes in dedicated STEM instruments.

The most common information that can be obtained from EELS spot analysis is:

- the local chemical composition and
- local atomic bonding and valence characterization.

### Local Chemical Analysis

As discussed in the introduction, core excitation edges appear in the spectrum at element characteristic energies. Therefore, EEL spectra can directly be used for qualitative analysis of the local chemical composition. Solid-state effects might slightly shift the edge position depending on the specific electron structure of the material. However, this chemical shift does not generally exceed 5 eV, which, in the majority of cases, cannot cause wrong identification of the element. Quantification of the spectra then proceeds with removal of background and multiple scattering to yield element ratios.

### Local Bonding and Oxidation State

Near the threshold, ionization edges often show fine details, called ELNES, which contains information about the electronic structure of the probed material. In the event of ionization, electrons from a core shell are excited into unoccupied states above the Fermi level. Just near the threshold these states represent an unoccupied part of the conduction band, which is sensitive to changes of bonding and oxidation state in solids. Thus, it is possible to track bonding and

oxidation state trends at an extremely small scale by comparing nanoprobe EEL spectra with theoretical calculations or with experimental reference spectra. The latter is generally called fingerprinting and is widely used for identification of specific compounds. An example is given in **Figure 3** where the C K-edges from graphite and diamond can be easily distinguished by comparing the ELNES patterns. In graphite, a sharp peak associated with the  $\pi^*$  orbital is found a few electronvolts before the major group of peaks associated with  $\sigma^*$  orbitals. In many cases, however, the interpretation of the ELNES is not so straightforward and theoretical calculations are needed to relate the ELNES features with the bonding and oxidation state.

Following the inelastic scattering theory, the scattering cross-section can be expressed as

$$\sigma \propto \int \frac{d\vec{q}}{q^3} \sum_f |\langle f | e^{i\vec{q} \cdot \vec{r}} | i \rangle|^2 \quad [6]$$

where  $\vec{q}$  is the scattering vector,  $i$  and  $f$  are initial and final electron states, and the summation is performed over all possible unoccupied final states above the Fermi level. The term  $|\langle f | e^{i\vec{q} \cdot \vec{r}} | i \rangle|^2$  in the integral is significant only in an area where initial and core states spatially overlap. The initial core state is highly localized around a nucleus, thus the conduction band is probed selectively for each given atom position. The term  $e^{i\vec{q} \cdot \vec{r}}$  can be expanded as  $1 + \vec{q} \cdot \vec{r} + \frac{1}{2}(\vec{q} \cdot \vec{r})^2 + \dots$  and neglecting the terms higher than first

order results in significant simplification of eqn [6] called the dipole approximation. In the dipole approximation, the term  $|\langle f | \vec{r} | i \rangle|^2$  does not vanish only if the angular momentum  $l$  of the final state differs by one from the angular momentum of the core state. Thus, only final states with a selected angular momentum  $l$  are probed. A K-edge ( $l_0 = 0$ ) probes only unoccupied p-states with  $l = 1$  while  $L_{2,3}$ -edges ( $l_0 = 0$ ) probe both unoccupied d-states ( $l = 2$ ) and s-states ( $l = 0$ ) with a higher probability for going to d-states. The dipole approximation has been proved to be valid for small  $\vec{q}$  while for high scattering  $\vec{q}$  vectors dipole forbidden transitions can be observed. Furthermore, it can be shown that in the dipole approximation the energy differential cross-section is expressed as

$$\frac{\partial \sigma(E)}{\partial E} \propto N_{l_0+1}(E)A_{l_0+1}(E) + N_{l_0-1}(E)A_{l_0-1}(E) \quad [7]$$

where  $N_l(E)$  is the density of empty states with a given angular momentum  $l$  in the conduction band and  $A_l(E)$  is a term slightly dependent on energy. As mentioned above, in most cases, only the transition  $l_0 \rightarrow l_0 + 1$  needs to be considered. Equation [7] reveals that under certain conditions the energy differential EELS cross-section is roughly proportional to the angular momentum projected unoccupied local density of states  $N_l(E)$ . This is schematically sketched in **Figure 4**, in which ELNES peaks on the top of a given EELS ionization edge can be related

**Figure 3** ELNES fine structure for carbon and diamond. Although both edges are excitations from the 1s-state of carbon, the different unoccupied final states for both compounds create significant differences in the fine structure of the edges.

**Figure 4** Correspondence between the fine ELNES structure and the DOS in the empty part of the conduction band.

with the density of states (DOS) shape in the empty part of the conduction band.

### Numerical Calculations

Several approaches were developed for numerical calculations of the scattering cross-section. In the simplest approximation of a free atom, the final states are assumed to be not affected by the other atoms in the crystal and can be presented as unoccupied bound atomic states and free electron states. Atomic calculations predict well the energy dependence of the EELS cross-sections far above the threshold and are widely used for quantitative chemical analysis (see above). As clearly seen from **Figure 2**, atomic cross-sections fail to reproduce the near-edge structure, which is strongly affected by solid-state effects. The latter can be accounted for by considering the interference of the outgoing ionized free electron wave with waves backscattered from the neighboring atoms. These calculations, called multiple-scattering calculations, reproduce successfully the features of the near-edge structure provided a sufficient number of neighboring atoms is considered. This method operates with atomic clusters in real space and allows one to treat disordered and aperiodic systems like alloys, interface, and surfaces. The main limitation arises from the rapid increase of the calculation time with growing cluster size.

Alternatively, standard electron band calculations like augmented plane waves, linearized augmented plane waves, or pseudopotential methods can be employed. Pseudopotential methods using plane waves and a smooth crystal potential are quick and sufficiently

precise in calculating the final states. These methods, however, cannot treat explicitly the core electrons. Fortunately, in the majority of cases, this is not required as the core electrons are not noticeably affected by crystal fields and are almost the same as those in free atoms. Another group of methods divides the crystal into muffin-tin (MT) spheres and interstitial space. The single particle electron functions are decomposed into the radial functions in the MT spheres and in plane waves in the interstitial region. In such a way the crystal potential produced by both core and outer electrons can be self-consistently calculated using the economic wave function basis yielding a reasonable computation time.

One of the most commonly used computer programs for all-electron calculations is the WIEN code. Except calculating the dipole-forbidden transitions, WIEN can also simulate the  $q$ -dependence of scattering and the effect of the orientation of crystalline material. An example of EEL spectra simulated by WIEN is shown in **Figure 5**. The major peaks in the ELNES of TiO and TiO<sub>2</sub> are well predicted by the *ab initio* calculations although there is still some disagreement in the exact peak positions and their relative intensities. The reason for this is that calculations describe the stationary ground state of an atom while the EEL spectra rather relate to the excited state where the initial unperturbed and the final ionized state are quantum-mechanically superposed. Taking into account the effect of a core hole remaining in the inner shell after excitation of an electron has been demonstrated to improve significantly the agreement with the experimental curves. However, the methods for accounting the core hole

**Figure 5** Theoretical profiles (ELNES) of the Ti L edge in the  $\text{TiO}_2$ -rutile and TiO compared with experimental ELNES from 100 nm particles. No core-hole effect is accounted for.

effect are still not well established and remain under discussion.

## Image Analysis

The technique of obtaining images of specific elements, the so-called elemental maps, is another important application in EELS analysis. Energy filtered TEM (EFTEM) images can be obtained with a so-called imaging spectrometer. However, the images are not directly interpretable as chemical maps because of the nonspecific background in the EELS spectrum.

Two techniques exist to solve this problem by taking more than one image: the three-window technique and the so-called jump-ratio technique. The first approach requires three images for elemental mapping while only two are needed in the second method. The method of the three windows allows one to make an image of which the intensity is proportional to the intensity in the EEL spectrum under a certain excitation edge. The method makes use of three images made up of electrons coming from three different energy regions in the spectrum. Two pre-edge images are used to estimate the non-specific background in each pixel of the image, by

estimating the parameters of the background model  $A \cdot E^{-r}$  for each pixel in the spectrum. The third image (post-edge image) is obtained from the energy region that contains the excitation edge of interest. The estimated background for each pixel is subtracted from the post-edge image and an excitation-specific image remains. The resulting image then contains an intensity per pixel, which is proportional to the number of electrons that have made the specific excitation. If the cross-section is known for the excitation in the specimen (for given experimental conditions), it is then possible to estimate the absolute concentration of a given element. Important parameters for the use of this three-window technique are:

- the position of the energy selecting window;
- the width of the energy window;
- the number of counts in the images (they should be as high as possible but too long exposure times and overexposure should be avoided);
- the spatial and energy drifts during the acquisition of the images (drift between the images can be corrected by using a cross-correlation technique);
- the type of excitation used (the greater the cross-section for an excitation the better the elemental mapping will work); and

- the thickness of the specimen (comparing regions of comparable thickness is more accurate and easier to interpret).

The optimal settings for these parameters depend on the goal of the experiment.

An alternative to the three-window technique is the so-called jump-ratio technique. In this case, two EFTEM images are recorded: one pre-edge and one post-edge. Dividing the post-edge by the pre-edge image leads to a jump-ratio image. This image gives a qualitative image of the changes in the spectrum between the pre-edge and post-edge regions. No quantitative data can be extracted since the ratio of background plus edge is not directly related to the excitation edge strength but also depends on the background. The advantages of using this technique over the three-window method are:

- A better signal-to-noise ratio in the final image is obtained, since no extrapolation or parameter estimation is needed.
- The image is less sensitive to preserved elastic contrast in the EFTEM images. The ratio cancels out all elastic contrast information that is the same for both pre- and post-edge images.
- Drift problems are reduced since only two images are needed.

The disadvantage, of course, is the loss of quantitative information. Therefore, this technique is only used to discern real chemical changes from elastic contrast effects by comparing the result of the jump-ratio image to the elemental image. In general, it is useful to avoid zone-axis orientations in EFTEM work to limit elastic contrast effects.

**Figure 6** EFTEM image partially pasted on a TEM image of a semiconductor test structure showing the different elements present in the specimen as color coded.

A convenient way to present and compare elemental maps of different elements from the same sample are the so-called color coded maps. These images are prepared by overlaying up to three elemental maps using a different primary color for each. The total image is then a color coded image, with mixed colors where more than one element is present in the same region. The advantage is that the correlation between the different elemental maps is much more visible, compared to the presentation of the different elemental maps as separate gray-scale images (Figure 6).

The spatial resolution in EFTEM images can be as good as 1 nm if a careful selection is made of the apertures in the microscope and specimen drift is kept to a minimum. A good understanding of the imaging process is necessary to obtain high-resolution EFTEM images but treatment is beyond the scope of this article.

Electron spin resonance (ESR) spectroscopy is also known as electron paramagnetic resonance (EPR) spectroscopy and less often, but more desirably, as electron magnetic resonance (EMR) spectroscopy. The last name highlights the similarities with nuclear magnetic resonance (NMR) spectroscopy. In fact, both ESR and NMR share the same basic theory. Whereas NMR deals with nuclei having magnetic moments, ESR refers to electrons, but these must be unpaired. At first sight this requirement appears to be a severe limitation on the usefulness of ESR, but the reality is that a wealth of information can be obtained from this branch of spectroscopy. A large number of transition metal compounds, both with odd and even numbers of electrons, are paramagnetic and thus can be studied by ESR. There are many chemical compounds that have odd numbers of electrons – namely, organic and inorganic free radicals. Other systems having unpaired electrons are molecules in electronic triplet states, impurities in semiconductors, electrons in unfilled conduction bands, and electrons trapped in radiation-damaged sites. Thus there are an enormous number of applications ranging from new materials to biochemical systems – some of these applications will be considered in this article.

### Theory

The fundamentals of the magnetic resonance phenomenon for nuclei and for electrons can be described both in quantum mechanical and in classical terms. The latter description is particularly useful when considering spin physics and pulse methods. Both descriptions lead to the resonance condition, for a particle having a spin value of  $1/2$ :

$$\Delta E = g\mu B \quad [1]$$

where  $\Delta E$  is the separation of energy levels produced by the application of an external magnetic field,  $B$ ,  $g$  is the  $g$ -factor (a tensor quantity), which has a value of 2.0023 for a free electron and 5.5856 for a proton. The magnetic moment  $\mu$ , is given by

$$\mu = eh/4\pi m \quad [2]$$

where  $e$  and  $h$  are fundamental constants and  $m$  is the mass of the particle. For the electron,  $\mu$  (the Bohr magneton) has a value of  $9.274 \times 10^{-24} \text{ J T}^{-1}$  while for the proton,  $\mu$  (the nuclear magneton) has a value of  $5.051 \times 10^{-27} \text{ J T}^{-1}$ . These values illustrate one of the main differences between ESR and NMR, that is, the sensitivity.  $\Delta E$  is  $\sim 600$  times larger for the electron, hence ESR is much more sensitive than NMR; for example, it is possible to record ESR spectra for  $10^{-7} \text{ mol l}^{-1}$  solutions of stable free radicals.

### $g$ -Factors

In a molecule, the unpaired electron may occupy an orbital that may be more or less localized on a single

atom, for example, in the methyl radical the unpaired electron is localized almost entirely in a p orbital at right angles to the plane of the molecule. The electron may also be virtually delocalized over the entire molecule, as in the case of the naphthalene negative ion. The  $g$ -factor can provide information on such delocalization since it is dependent on the spin-orbit coupling:

$$g = L + g_0S \quad [3]$$

where  $g_0 = 2.0023$ ,  $L$  is the total orbital angular momentum, and  $S$  is the total spin angular momentum: for large values of  $L$ ,  $g$ -factors can be as high as 9 or more. The value of  $L$  is particularly important for free radicals containing heavy atoms and for paramagnetic transition metal compounds. For the latter compounds the orbital contributions are very similar to those observed in measurements of magnetic moments of metal complexes. Since the  $g$ -tensor will clearly be anisotropic if  $L$  is not zero, linewidths of solution spectra can be affected and solid-state spectra can depend upon the orientation of the sample.

$g$ -Factors can also be affected by mixing of ground electronic states with excited states that have orbital angular momentum. The extent of the mixing is inversely related to the energy of the excited state, which may be represented by the equation:

$$g = 2.0023(1 - f\lambda/\Delta E) \quad [4]$$

where  $\lambda$  is the spin-orbit coupling constant,  $f$  is a composite numerical factor, and  $\Delta E$  is the separation of the ground and excited electronic states. Equation [4] is especially important for transition metal complexes: for atoms with fewer than five d electrons,  $\lambda$  is positive, it is zero for five electrons, and it is negative for more than five d electrons. The magnitude of  $\lambda$  depends upon the oxidation state of the atom, but it also increases rapidly with increase of atomic number, so the effect is large for the later 3d atoms and very large for the 4d and 5d atoms.

### Fine Structure

Transition-metal complexes can have more than one line in their spectra due to the fact that more than one unpaired electron may feature in the complex. The extra lines arise from zero-field splitting, which depends upon molecular structure, the extent of spin-orbit coupling and other factors. It is common for the zero-field splitting to be very large; in which case, either no resonance is observed or there is only one line in the spectrum.

A complex ESR spectrum is observed when there are hyperfine interactions due to the presence of

magnetic nuclei – the effect is analogous to the nuclear spin-spin interactions found in NMR spectra: in ESR spectroscopy the extra lines are referred to as hyperfine structure. A nucleus of spin value  $I$  gives  $2I + 1$  lines all of equal intensity and separated by the hyperfine coupling constant  $a$ . (It should be noted that extra lines and uneven separation of lines can occur when second-order effects are present: these effects come into play when the magnitude of  $a$  is large and approaches that of the applied magnetic field). The magnitude of  $a$  depends upon the unpaired electron spin density located at the magnetic nucleus in question. For nuclei having a positive magnetic moment, and under the influence of a large unpaired electron spin density,  $a$  is positive; however,  $a$  can be negative if the spin density is small since low spin densities can be negative. Spectra can be very complicated when there is interaction from a number of magnetic nuclei. There are three major factors which control the magnitude of  $a$ . The first is the Fermi contact term, which operates through the s character of the unpaired electron, there being a finite probability of s electrons being located at the nucleus. This term is important for transition metal complexes only when there is low symmetry because the unpaired electrons are formally d electrons and mixing of d and s electrons can only occur when they have the same symmetry. A second factor is the spin-polarization effect in which the unpaired spin density in valence orbitals polarizes the distribution of electrons in the core orbitals. The third factor operates in the solid state – it is the electron-nucleus dipolar coupling. This depends upon the distance between the unpaired electron and the magnetic nucleus and also upon their relative orientations. The orientation of the nuclear spin is determined by the applied magnetic field, while that of the unpaired electron depends upon its orbital character and the orientation of the molecule with respect to the applied magnetic field. It is obvious that dipolar coupling produces anisotropy in the hyperfine interaction leading to the three principal magnitudes  $A_{xx}$ ,  $A_{yy}$ , and  $A_{zz}$  (these are diagonal elements in a matrix): they can be positive or negative. Thus for a solid, the hyperfine interaction  $A$  is made up of two main terms, namely  $a + T$ , where  $a$  is the isotropic hyperfine interaction and  $T$  is the anisotropic hyperfine interaction. In a single crystal, both  $A$  and  $g$  can change with orientation. For powdered solids or frozen solutions, all orientations are represented in the spectrum but the principal values of  $A$  are associated with their corresponding  $g$ -factors. **Figure 1** illustrates the difference between a powder spectrum and a single crystal spectrum of a copper(II) complex diluted with the compound

**Figure 1** First-derivative powder and single crystal (at four orientations) X-band ESR spectra of copper(II) in  $\text{CaCd}(\text{CH}_3\text{COO})_4 \cdot 6\text{H}_2\text{O}$ . The powder spectra show that parallel (||) features are absorption-like and they correspond to the  $\theta = 0^\circ$  orientation in the crystal spectra. (Reproduced with permission from Pilbrow JR (1990) *Transition Ion Electron Paramagnetic Resonance*. Oxford: Clarendon Press, Oxford University Press.)

$\text{CaCd}(\text{CH}_3\text{COO})_4 \cdot 6\text{H}_2\text{O}$ : the fine structure comes from two copper nuclides both having a nuclear spin of  $3/2$  and similar magnetic moments. The full detailed structure in a spectrum may not always be resolved and a broadening of lines is observed. For solutions, the dipolar coupling is averaged to zero so that:

$$a_{\text{iso}} = [(a + T_{xx}) + (a + T_{yy}) + (a + T_{zz})]/3 \quad [5]$$

There may be small discrepancies between this average and the true value of  $a_{\text{iso}}$ . Evaluation of  $a$  and  $A$  allows estimations to be made, respectively, of  $s$  and  $p$  spin densities centered upon a particular magnetic nucleus. **Figures 2** and **3** illustrate the different ESR spectra obtained from a solution in the liquid and frozen states of the free radical 1,3,2-dithiazolo-[4,5-*b*]quinoxalin-2-yl (QDTA). The spectrum shown in **Figure 1** is characterized by one value of  $g_{\text{iso}}$ , a large isotropic hyperfine interaction from the nitrogen nucleus at position 2 that gives rise to the three groups of lines: the fine structure within each group comes from the two equivalent nitrogen nuclei at positions 1' and 4' and from the aromatic protons. Thus all the abundant magnetic nuclei in the molecule contribute to the spectrum. The frozen solution

**Figure 2** First-derivative X-band ESR spectrum of 1,3,2-dithiazolo-[4,5-*b*]quinoxalin-2-yl in toluene- $d_6$ :acetone- $d_6$  (4:1, v/v) at 128 K: (A) is the experimental spectrum and (B) is the computer-simulated spectrum.

**Figure 3** First-derivative X-band ESR spectrum of 1,3,2-dithiazolo-[4,5-*b*]quinoxalin-2-yl in toluene:acetone (4:1, v/v) at 222 K.

spectrum shown in **Figure 3** (both the experimental spectrum and the computer-simulated spectrum are given) is characterized by three anisotropic  $g$ -factors and by the corresponding anisotropic hyperfine interactions,  $A_{xx}$ ,  $A_{yy}$ , and  $A_{zz}$  for the nitrogen nucleus at position 2 and for the nitrogens at positions 1' and 4'. From the markers at the foot of **Figure 3** it may be seen that the latter pair of nitrogen nuclei have negligible hyperfine interactions in the  $y$ - and  $z$ -directions. In fact, the major interaction for all the nitrogens is in the  $x$ -direction, which is at right angles to the plane of the molecule, and this tells us that nitrogen  $p_x$  orbitals are responsible for the interaction. Because hydrogen nuclei have negligible anisotropic interactions they do not feature in the solid-state spectrum.

### Linewidths

The theoretical width of an ESR line is  $\sim 0.01$  mT and this may be approached in solutions of free radicals as shown in **Figure 2**. However, various relaxation

processes can shorten the lifetime of an excited state and cause line broadening. Electron spin–lattice and spin–spin relaxation times can be very short, which is why pulse methods are difficult to implement in ESR spectroscopy and why spectra of solid-state transition metal complexes are often broad and poorly resolved. It will be noted that the line-heights of the three main groups of lines in **Figure 2** are different or in other words, the lines are broader towards high fields. This is due to the rate of tumbling of the radical being insufficiently rapid to average out the anisotropic contributions. Other molecular dynamics processes can cause alternate lines in the spectrum to be broadened – this is known as the alternating linewidth effect. There are a wide variety of such processes which can affect the linewidths in these ways and they include electron spin exchange, electron transfer, proton exchange, ion association, and molecular inter-conversion. Though these effects contribute to the complexity of ESR spectra, analysis of the data they provide can yield very valuable structural and kinetic information.

## Instrumentation

The microwave radiation used in ESR is most commonly of frequency  $\sim 9\text{--}10\text{ GHz}$  [i.e.,  $(9\text{--}10) \times 10^9\text{ s}^{-1}$ ] – the so-named ‘X-band’ – but other frequency ranges are sometimes used. When a different choice of microwave frequency is made, a different strength of the external magnetic field is required to achieve the resonance condition. This follows from eqn [1]. Since the innate sensitivity of ESR depends on the excess of spins in the ground state, which relates to the Boltzmann factor, it is clear that measurements made at lower microwave frequencies will afford an intrinsically weaker signal. There are, however, very good reasons for undertaking so-called ‘multi-frequency’ experiments. For example, in the study of large biological or aqueous samples (including isolated organs, such as the liver, and whole, small animals), a frequency of  $\sim 1.5\text{ GHz}$  (L-band) is often beneficial. This is because the absorption of microwave radiation by water becomes increasingly attenuated on reduction of its frequency. It is also important to be aware of the ‘dimensions’ attendant to the experiment: namely the size of the resonant cavity. At X-band, the frequency ( $\nu$ ) is  $\sim 9.5 \times 10^9\text{ s}^{-1}$ , which corresponds to a wavelength ( $\lambda$ ) of 3.2 cm. In order to set up a resonant (standing) wave, the cavity must also be of this dimension. At L-band, since  $\nu = 1.5 \times 10^9\text{ s}^{-1}$ , the size of the cavity is now 20 cm (8 inches!), and so a far larger sample

might be accommodated. Allowing, overall, for the loss of sensitivity caused by the reduced Boltzmann factor at the lower frequency, and the compensation for which is possible with a much larger sample volume, a working rule is that an L-band experiment is of around a factor of ten lower in sensitivity than the one at X-band. Similar reasoning applies to measurements made at higher frequencies. For example, at W-band,  $\nu = 9.4 \times 10^{10}\text{ s}^{-1}$ . In this case,  $\lambda = 0.32\text{ cm}$  ( $\sim 3\text{ mm}$ ), and the sample is usually contained in a tube of overall diameter  $\sim 1\text{ mm}$ , with an internal diameter of  $\sim 0.6\text{ mm}$ . While it is true that the experiment is ideal for (highly expensive) biological materials, available only in small quantities, and that the greatly increased Boltzmann factor will largely offset the loss of sensitivity from such a small sample, the actual signal intensity is limited by problems of magnetic field inhomogeneity and component construction. The commonly encountered microwave frequencies, their wavelength equivalents, and representative attendant magnetic fields required for resonance, are all listed in **Table 1**, although we note that ESR experiments have been done at frequencies up to  $\sim 500\text{ GHz}$ .

Multi-frequency methods are generally resorted to in an effort to improve the resolution of a given ESR spectrum. In the solid state, it is sometimes unclear whether an apparent splitting arises from different g-components, or is due to hyperfine coupling. By increasing the frequency, the separation of g-components is increased, but a hyperfine splitting will be unaffected. Measurements made over a range of frequencies are also sometimes useful in achieving a more optimal separation of spectral features in transition metal complexes, and may also provide a useful range of ‘time-windows’ in studies of molecular reorientation (e.g., of spin-labels or spin-probes).

Pulse methods dominate over (CW) methods in the instrumentation used in NMR spectroscopy, while the reverse is true for ESR. The problem in adopting pulse methods for the latter arises for two main reasons: (1) a typical ESR spectrum of a free radical occupies  $\sim 90\text{ MHz}$ , and (2) spin–lattice relaxation

**Table 1** Frequency ranges, wavelengths, and representative resonant magnetic fields for different microwave bands

Band	$\nu$ (GHz)	$\lambda$ (cm)	$B$ (G)
L	1.5	20	500
S	3	10	1000
X	9.5	3.2	3400
K	24	1.3	8500
Q	35	0.8	12500
W	94	0.3	33500

times of free radicals are of the order of microseconds. Thus to obtain a complete ESR spectrum from a single pulse would require very large microwave powers and digitization of the spectrum in 1 ns. Some of the problems can be circumvented and commercial pulse ESR spectrometers are available but they are not as ubiquitously useful as their NMR counterparts.

A block diagram of a simple CW ESR spectrometer is shown in Figure 4. The basic components are a frequency source (klystron or Gunn diode), an electromagnet (having a field of  $\sim 330$  mT for X-band), and a resonant cavity (or loop gap resonator) in which to place the sample. The microwave source and the crystal detector are normally contained within one unit known as the microwave bridge. The microwaves are introduced into the sample cavity via a waveguide and the reflected radiation returns to the microwave bridge. The magnetic field is swept rapidly with a set of small coils mounted on the cavity for oscilloscope display of the signal, or the main field is swept slowly for pen recorder presentation. In order to improve the signal-to-noise ratio it is customary to modulate the microwave frequency at 100 kHz and detect at this frequency with a phase-sensitive detector. The result of doing this is to produce first-derivative absorption spectra as exemplified by Figures 1–3. Other components of an ESR spectrometer can include equipment for controlling the temperature of the sample from 4 to  $\sim 1000$  K, a field-frequency lock, NMR gaussmeter (for accurate magnetic field measurement), microwave frequency counter, data acquisition system, and computer control of the entire operation of the spectrometer.

**Figure 4** Block diagram of a simple continuous-wave ESR spectrometer.

For almost all ESR studies, high-purity silica is used to contain the sample and to fabricate the Dewar flask placed in the sample cavity for variable-temperature work. The major advantage of silica is that it is free from the paramagnetic iron and vanadium impurities found in borosilicate glasses: there is an additional advantage in that it helps to focus the microwave field in the sample cavity and thus the sensitivity is improved. High-purity silica does not readily generate paramagnetic defects when the sample is to be irradiated with ionizing radiation such as  $\gamma$ -rays. Flat cells or capillaries are used for lossy samples. Special cells are available for *in situ* electrochemical experiments and for rapid and stopped flow measurements. Most sample cavities have a 'window' to allow photochemical experiments to be carried out. The highest radical solution concentration, which is advisable to use, is  $10^{-4} \text{ mol l}^{-1}$  in order to avoid exchange broadening: concentrations for solids can be as high as  $10^{-2} \text{ mol l}^{-1}$ , which is low enough to prevent line broadening from dipole-dipole interactions. For single crystal work it is obvious that, as seen in Figure 1, a diamagnetic host crystal has to be used. For high-resolution studies of solutions, such as the example shown in Figure 2, it is essential to remove oxygen to reduce the effects of paramagnetic line broadening.

Most ESR spectroscopy is concerned with stable paramagnetic materials but, because of the high sensitivity of the technique, it can also be used to study short-lived species having half-lives as short as 1  $\mu\text{s}$ . Free radicals having half-lives in the millisecond region can be observed by flowing the reagents rapidly through a mixing chamber in the resonant cavity. Radicals which can be generated photochemically lend themselves to study with high-speed pulses from a laser.

## Applications

Several broad categories can be highlighted:

1. Transition metal complexes. These are studied for their intrinsic interest, and also in biological systems such as metalloproteins and in catalysts, for example when they are incorporated into zeolites.
2. Organic free radicals. There are many basic studies on these including structural investigations, their role as reaction intermediates, mechanistic studies, and studies of molecular dynamics. New free radicals are being synthesized for use in spin labeling and for use as spin probes. There is a tremendous amount of effort being put into using spin labels in biological work; they are used for

example to study the structure of membranes. Organic free radicals are produced when synthetic polymers undergo degradation.

3. Free radicals are formed when most materials are subjected to ionizing radiation, thus ESR can be used to monitor the process. In the food industry such monitoring is extremely important and ESR can assist in direct radical concentration measurement and also in providing a means of measuring the radiation dose. Radiation effects on rocks can be used to measure ages up to one million years.
4. Naturally occurring free radicals are found in all living systems and ESR provides a useful measure of these, for example the radical concentration in normal cells has been found to be higher than in cancer cells. Oxygen is responsible for the formation of some radicals in living systems, and ESR can be used to measure its concentration (oximetry). Spin traps are stable diamagnetic compounds which react rapidly with unstable free radicals to give a long-lived species that can be examined by ESR. The spin trapping technique is useful for studying a wide variety of chemical reactions as well as those of biological interest.

## Introduction

Most specialized electron spin resonance (ESR) techniques are largely instrumental but there are several techniques that are in widespread use that only require a standard ESR spectrometer for their application – two of these are spin trapping and spin labeling. Another important technique that is coming into use in biological work is oximetry. Details of the three techniques are given later.

Most of the specialized techniques involve the use of fairly sophisticated instrumentation; these can be divided roughly into two categories: continuous wave (CW) and pulse methods. Electron–nuclear double resonance (ENDOR) and ESR imaging will be discussed in the CW category, while a variety of

techniques (including pulse ENDOR) will be presented in the pulse section.

## Spin Trapping

A limitation to the application of ESR spectroscopy to the study of reactive intermediates in reactions is the difficulty of producing a sufficient quantity of free radicals for direct detection. The introduction of the technique of spin trapping has provided a simple and effective means of overcoming this difficulty. A diamagnetic compound (a spin trap) is introduced into the radical-producing system to give a relatively stable ESR-observable free radical (spin adduct). In favorable cases, the original free radical can be identified from the *g*-factor and hyperfine coupling constants of the spin adduct. The method allows studying free radicals that are being produced at low stationary-state concentrations (e.g., by  $\gamma$ -radiolysis) over a long period. Typical spin traps are nitroso compounds (1) or nitrones (2)

(1)

R is an alkyl or aryl group

example to study the structure of membranes. Organic free radicals are produced when synthetic polymers undergo degradation.

3. Free radicals are formed when most materials are subjected to ionizing radiation, thus ESR can be used to monitor the process. In the food industry such monitoring is extremely important and ESR can assist in direct radical concentration measurement and also in providing a means of measuring the radiation dose. Radiation effects on rocks can be used to measure ages up to one million years.
4. Naturally occurring free radicals are found in all living systems and ESR provides a useful measure of these, for example the radical concentration in normal cells has been found to be higher than in cancer cells. Oxygen is responsible for the formation of some radicals in living systems, and ESR can be used to measure its concentration (oximetry). ## Spin Trapping

A limitation to the application of ESR spectroscopy to the study of reactive intermediates in reactions is the difficulty of producing a sufficient quantity of free radicals for direct detection. The introduction of the technique of spin trapping has provided a simple and effective means of overcoming this difficulty. A diamagnetic compound (a spin trap) is introduced into the radical-producing system to give a relatively stable ESR-observable free radical (spin adduct). In favorable cases, the original free radical can be identified from the *g*-factor and hyperfine coupling constants of the spin adduct. The method allows studying free radicals that are being produced at low stationary-state concentrations (e.g., by  $\gamma$ -radiolysis) over a long period. Typical spin traps are nitroso compounds (1) or nitrones (2)

(1)

R is an alkyl or aryl group

$R_1$  and  $R_2$  can be an aryl group or a proton and  $R_3$  can be a *tert*-butyl group.

The reacting radical attaches itself to the nitrogen atom in a nitroso compound and to the unsaturated carbon in the nitron. The most commonly used nitroso compound is 2-methyl-2-nitrosopropane (MNP), while the most commonly used nitron is phenyl *N*-*tert*-butylnitron (PBN). When a methyl radical is trapped by MNP the resulting ESR spectrum is a 1:1:1 triplet of 1:3:3:1 quartets. However, if PBN is substituted for MNP the hyperfine structure is not indicative of the attached radical and its identity has to be deduced from hyperfine splittings originating from the nitrogen and lone proton already present in PBN. A nitron that is more sensitive to the structure of the incoming radical is 5,5-dimethyl-1-pyrroline-*N*-oxide. Nitrones have advantages over nitroso compounds in that they are thermally and photochemically more stable. Other disadvantages of nitroso compounds are (1) they have a tendency to form dimers that are inert toward radical trapping and (2) they are unreliable in applications involving oxygen-centered radicals. There is no such thing as a perfect spin trap; hence, it is necessary to be able to choose from a wide variety (more than 100 compounds have been proved to be suitable) for a particular application. One aid to the selection of a suitable trap is the availability of rate constants for many spin-trapping reactions.

Great care has to be taken in interpreting the results from spin-trapping experiments and they have to be augmented with thorough 'blank' experiments because it is possible to generate free radicals from spin traps in reactions in which free radicals are not involved.

## Spin Labeling

The principle of spin labeling is very simple – a macromolecule is attached to a stable free radical and the increase in molecular mass of the radical reduces its rate of tumbling, which can be easily monitored by ESR spectroscopy. The most suitable class of free radicals for the purpose are nitroxyls because of their stability and because the anisotropic  $g$  and  $A$  tensors are sufficiently different in the  $x$ -,  $y$ -, and  $z$ -directions to provide high sensitivity to a change in the rate of molecular tumbling. Rates of tumbling can be assessed, usually by computer simulation, by the change from a completely isotropic spectrum (rates

of  $\sim 10^{10} \text{ s}^{-1}$ ) to a near-powder spectrum (rates of  $\sim 10^6 \text{ s}^{-1}$ ). In order to attach itself easily to a macromolecule the nitroxyl radical has to be provided with a prosthetic group. Example (3) is a nitroxyl designed for attachment to a protein. Should a protein contain a thiol site with which the maleimide group can attach itself, then the ESR spectrum will change from a fast-tumbling to a slow-tumbling type. The method can be made quantitative so that a spin label solution can be 'titrated' against the protein solution. A great deal of skilled synthetic chemistry has been undertaken to provide specific spin labels.

A technique related to spin labeling uses spin probes to monitor molecular motion. In this technique, a radical is synthesized that mimics as closely as possible the structure of the molecule under investigation. Again nitroxyl radicals are the most suitable candidates. An example of their use is in the study of polymer melts: a spin probe is introduced into the polymer and then its rate of tumbling is measured as the polymer changes its viscosity and/or undergoes phase changes.

## Oximetry

In principle, the measurement of oxygen concentration in solution as small as  $10^{-6} \text{ mol l}^{-1}$  is possible. Since ESR linewidths are broadened by the presence of other paramagnetic substances such as oxygen, a radical possessing narrow lines can be used to measure the concentration of the latter. The ubiquitous nitroxyl radicals can be used in this application. Narrow lines can be achieved by keeping the number of magnetic nuclei to a minimum and by using deuterium instead of protium for those that cannot be avoided: the hyperfine splittings for deuterium are about one-sixth those of protium as a result of their different magnetogyric ratios.

Another approach is to use a solid that is permeable to oxygen and has a single very sharp line. This can be achieved extremely well with small crystals of

lithium phthalocyanine that, in the absence of oxygen, have a peak-to-peak linewidth less than 0.002 mT. This is so narrow that most commercial ESR spectrometers do not have sufficient stability to take full advantage. A less good, but much cheaper, material is a species of coal called fusinite.

## Quantitative ESR ('Q-ESR')

Obtaining reliable measurements of ESR signal intensities is extremely tricky, and it almost appears that all vital aspects of the ESR experiment act in conspiracy against managing this successfully! For a start, the sensitivity of the measurement depends acutely on the position of the sample in the microwave cavity, and is greatest at a single point at the cavity center. On moving the sample away from this point, in any direction, the ESR signal intensity is found to decrease. The sample tube can be constrained by means of a 'collet', so that movement only up and down in the cavity is possible. When the sample is a liquid (and therefore is homogeneous), potential problems in its positioning may be circumvented by using a completely filled sample tube that extends through the full length of the cavity. In this case, the exact position of the sample has far less influence on the signal intensity, provided that the sample tube is homogeneous in its diameter and wall thickness. For many solid materials, it is not possible to provide a 'homogeneous', cavity-length sample. Therefore, the sample position needs to be determined precisely. Various devices have been devised for this purpose; the simplest being merely to draw a calibration mark on the sample tube, so that its penetration depth through the collet and into the cavity is known and is consistent. For a series of samples, a set of matched tubes is required, each calibrated to the same depth, which ideally brings the sample to the cavity center, in order to maximize sensitivity.

For quantitative comparisons between samples, they should be as closely matched in composition as possible. This applies to the use of standard samples against which may be measured unpaired electron concentrations: these are more usually referred to as 'spin concentrations', and are quoted as the number of 'spins' (unpaired electrons) per gram of sample. So, at the very least, the sample tubes should all be filled to the same depth, and at best, the standard should consist of the same material as the sample. Since this is rarely possible, a more practical alternative strategy is to match the materials as closely as possible in their electromagnetic properties.

Finally, of course, the operating conditions of the ESR spectrometer, e.g., gain, modulation, and microwave power level, should be the same for both sample and standard, although the signal intensity response to the 'gain' is probably sufficiently linear to permit extrapolation from one sensitivity range to another, as is required when the two specimens have widely different spin concentrations. Strictly, the spin concentration should be determined against a standard, and, in principle, any paramagnetic material of known spin concentration might be used. In practice, 1,1-diphenylpicrylhydrazyl is widely used.

The spin concentration of the standard is determined from the quantity (number of molecules) present, and a corresponding 'area' under the absorption peak is obtained by double integration of the first-derivative spectrum. There are programs available for doing this if the spectra are first digitized. Then the sample is run, the spectrum is then also double integrated, and from the relative areas, the spin concentration of the sample may be deduced. This is not always necessary, and good results may be achieved on the basis of relative peak heights alone.

## ENDOR Spectroscopy

ENDOR spectroscopy offers enhanced resolution compared with conventional ESR; for example, isotropic hyperfine interactions as small as 0.004 mT can be measured. This enhanced resolution is achieved partly because the technique lies between ESR and nuclear magnetic resonance (NMR) and also because redundant lines are eliminated from the spectrum: essentially the ESR signal is monitored while sweeping through NMR frequencies. The simplification of the spectrum arises from the fact that each  $a$ -value produces only two lines in the spectrum, irrespective of how many nuclei contribute to that hyperfine coupling constant. Other advantages of the method are:

1. The hyperfine splittings of each nuclide are determined uniquely since the spectrometer is set at the appropriate NMR frequency.
2. Direct analysis of quadrupolar splittings can be made.
3. Spectra of individual radicals in a mixture can be disentangled.
4. Relative signs of hyperfine and of quadrupolar interactions can be determined.

ENDOR methods have been applied to the study of organic radicals in solution, transition-metal

complexes, and metalloproteins such as solids, glasses, frozen solutions, and in single crystals.

CW ENDOR is considered in this section; pulse ENDOR is dealt with below. The instrumentation is usually based around a computer-controlled CW ESR spectrometer and is commercially available. A radiofrequency coil, capable of handling up to 1 kW power, is used to introduce the NMR frequencies. The coil is contained in a special resonant cavity. Various modulation strategies are employed to improve the signal-to-noise ratio. In order to carry out the ENDOR experiment, the spectrometer is set for a given line in the ESR spectrum. The microwave power is increased to just beyond the saturation level, and then the selected NMR frequency is swept. Two NMR transitions are observed at the frequencies:

$$\nu = |\nu_n \pm a/2| \quad [1]$$

where  $\nu_n$  is the NMR frequency for the applied magnetic field of the ESR spectrometer and  $a$  is the ESR isotropic hyperfine coupling constant. Equation [1] applies when  $\nu_n > |a/2|$ ; however, when  $\nu_n < |a/2|$ , the two lines are centered at  $|a/2|$  and are separated by  $2\nu_n$ . **Figure 1A** shows an ESR spectrum characterized by just two  $a$ -values and **Figure 1B** shows the simplification brought about in the ENDOR spectrum. Other experiments can be carried out with an ENDOR spectrometer. In the special and general TRIPLE experiments (electron–nuclear–electron triple resonance), three frequencies are employed. In the special experiment, two NMR transitions belonging to one set of equivalent nuclei are irradiated, while in the general case different sets of nuclei are irradiated (**Figure 1C**). The former experiment gives improved spectra compared with ordinary ENDOR. The general TRIPLE experiment provides a means of determining the relative signs of hyperfine coupling constants (not possible from an ESR spectrum). In the example shown in **Figure 1D**, the hyperfine coupling constants have opposite signs. The ENDOR-induced ESR (EIE) technique is used to distinguish between radicals in a mixture. Here, the NMR frequency is positioned at the top of an ENDOR line and the intensity changes of this line are monitored while the external magnetic field sweeps over the range of the ESR spectrum. The EIE spectrum has the appearance of an absorption spectrum (see **Figure 1E**). With the technique it is even possible to distinguish between different isotopically substituted radicals.

## ESR Imaging

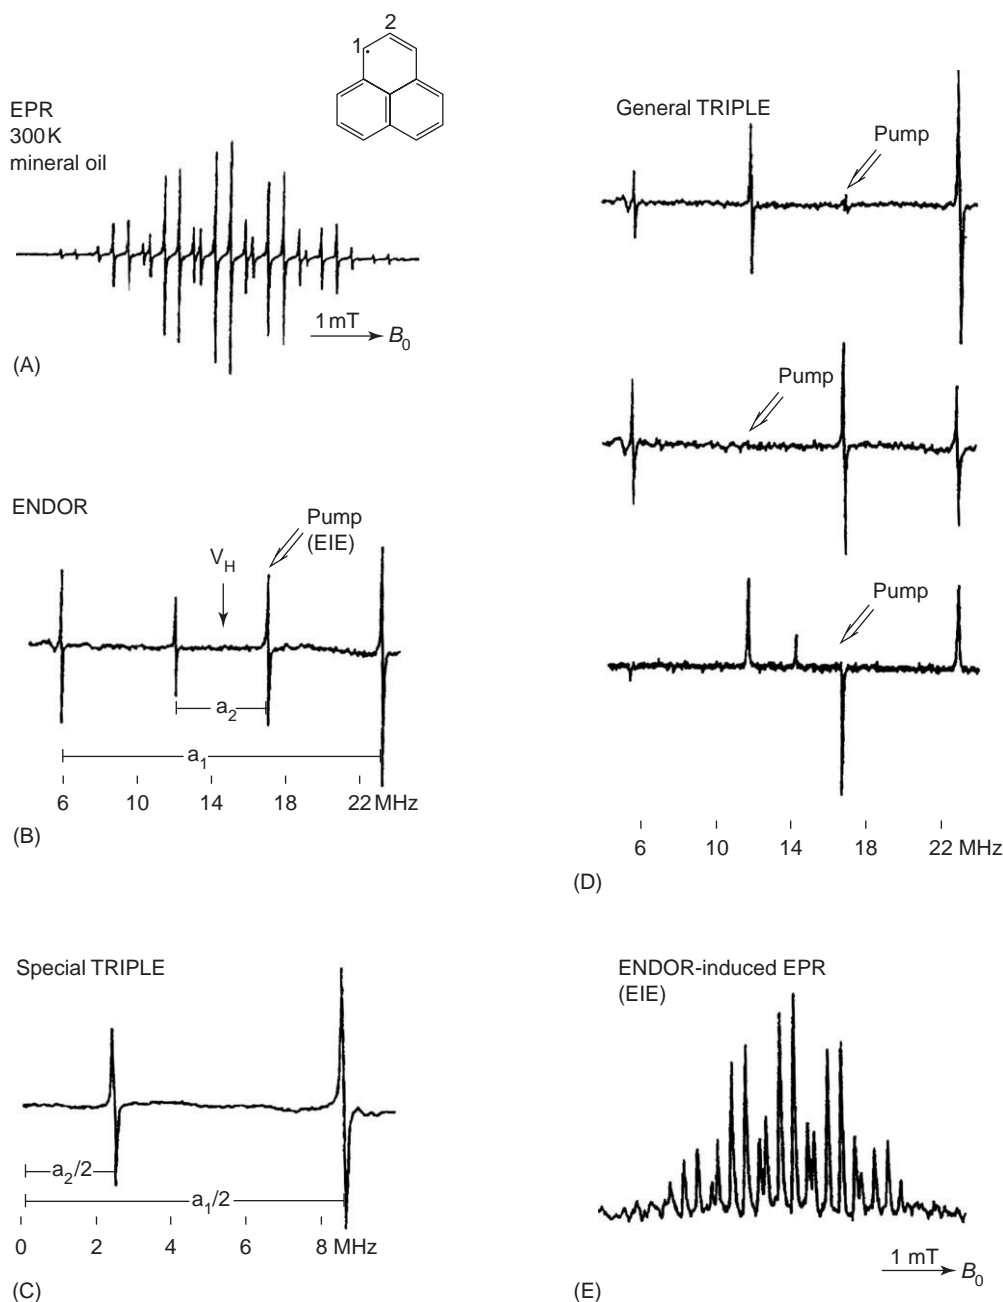

NMR imaging is now a well-established technique for both medical and materials research. The

principles are similar for NMR and ESR imaging – field gradients are used in the  $x$ -,  $y$ -, and  $z$ -directions to allow a volume element to be selected. Difficulties arise in ESR because the field gradients have to be much larger since an ESR spectrum occupies a much larger frequency range than does an NMR spectrum. Another problem arises due to the irradiating frequency used. As stated earlier, the most convenient frequency is  $\sim 9$  GHz, but this only allows a sample of maximum diameter 10 mm to be examined. This is satisfactory for ESR microscopy but is too small for the larger specimens encountered in biological research. For this purpose, frequencies as low as 200 MHz are being used, which permit samples as large as 100 mm to be investigated.

## Pulse Techniques

The basic principles of ESR and NMR are similar and thus one would expect pulse ESR to have a place in magnetic resonance. It does, but it cannot be expected to be as useful as pulse NMR because of practical difficulties. For example, the pulse power required to produce the frequency span of an ESR spectrum is  $\sim 20$  kW. The pulse would last for 1 ns and the signal would have to be digitized in this time. Methods have been devised to overcome these problems, the most common of which are based on spin echoes (echo techniques were developed in the early days of NMR). Echo-detected ESR spectroscopy can be very useful in detecting short-lived radicals generated, say, from a laser flash, where the time resolution is determined solely by the interval between the laser flash and the first spectrometer pulse. Using electron spin echo (ESE) spectroscopy, ENDOR spectra can be obtained from the Fourier transform of the echo-decay envelope. In contrast to CW ENDOR, the ESE envelopes always show deep modulation for the off-principal axis and little or no modulation for canonical orientations; hence, electron spin echo envelope modulation (ESEEM (also known as ESEM)) is a valuable supplement to CW ENDOR. **Figure 2A** shows the spectrum obtained from an ESEEM experiment on a single crystal of nickel(acacen) doped with cobalt(acacen) (acacen is  $N,N'$ -ethylene-bis(acetyl-acetate iminato)). The ENDOR spectrum that is obtained by carrying out a Fourier transform of these data is shown in **Figure 2B**.

The pulse ESR spectrometer is usually based on a standard CW spectrometer because a standard ESR spectrum is often required before carrying out the pulse experiment. The pulse part of the equipment is

**Figure 1** First-derivative spectra obtained by continuous-wave techniques for the phenalenyl radical: (A) ESR, (B) ENDOR, (C) special TRIPLE resonance, (D) general TRIPLE resonance, and (E) ENDOR-induced ESR. The arrows indicate the positions of the RF pumping frequencies: there are several possibilities in (D). The RF pumping frequency in (E) is set in the same position as shown in (B). (Reprinted from Kurreck H, Kirste B, and Lubitz W (1988) *Electron Nuclear Double Resonance Spectroscopy of Radicals in Solution*. Weinheim: VCH Publishers.)

quite sophisticated in order to overcome some of the problems mentioned above. Some of the components, such as the traveling wave tube amplifier, are expensive; thus, the whole spectrometer can be costly, but no more costly than a medium-priced well-equipped NMR installation.

## Applications

### Spin Trapping

The main use of spin trapping is clearly in identifying radical intermediates in organic and inorganic

**Figure 2** Section of a three-pulse ESEEM for a single crystal of [Ni(acacen)] $0.5\text{H}_2\text{O}$  doped with [Co(acacen)] at 4.2 K. (A) The ESEEM spectrum; (B) the Fourier transform of (A) showing the transition frequencies of the nitrogens and some of the protons. (Reprinted from Schweiger A (1986) *Moderne methodische entwicklungen in der Electronenspinresonanz-Spektroskopie. Chimia* 40: 111–123.)

reactions. The reactions can take place in the gas phase or in solution. The reactions can be thermal, electrochemical, or radiation induced. Probably the most important application of spin trapping is to the study of radicals in biological systems. Some examples of the latter are the effects of ionizing radiation on aqueous solutions of peptides, amino acids, and nucleic acids, and the detection of  $\text{O}_2^{\bullet-}$  and  $\text{OH}^{\bullet}$  radicals in lipid peroxidation.

### Spin Labeling

The method provides a means of studying biochemical and biophysical characteristics of many lipids, proteins, and amino acids. Many investigations have been devoted to the synthesis of radicals having a suitable reactive functional group to couple as selectively as possible and with minimum perturbation of the biological system. The latter requirement

is particularly important when a drug moiety is converted to a spin label for use in detecting the drug–antigen complex. The technique has been developed to provide spin immunoassay and spin membrane immunoassay.

Carbohydrates have been labeled to help elucidate the structures of enzymes, lectins, and epimers, and they have also been used as spin probes for cell membrane structures.

Stable nitroxyl radicals have also been widely employed as spin probes for the study of relaxation and molecular dynamics of synthetic polymers.

### Oximetry

Probably the most important application of the technique is in the study of animals *in vivo*. For the nitroxyl type of oxygen sensor it is necessary to use an imaging technique and then an oxygen concentration map can be constructed. Imaging is not so important when solid sensors are used, as small particles can be injected into the organ of interest. When a crystal of lithium phthalocyanine is injected into a rat heart, the change of oxygen concentration with each heart-beat can be monitored.

### Quantitative ESR

Obtaining a reliable measure of the number of unpaired electrons ('spin concentration') in a sample is often extremely useful. Even reliable relative values measured across a series of samples can often provide useful information. There are various important applications, as may be illustrated by the following incomplete list: ESR dating, the determination of oxidized polycyclic aromatic hydrocarbons and of environmental carbon in samples of ambient air, the influence of air pollution (e.g.,  $\text{SO}_2$  and  $\text{NO}_2$ ) on plants and soils, quantification of  $\text{NO}_2^{\bullet}$ ,  $\text{RO}_2^{\bullet}$ , and  $\text{HO}_2^{\bullet}$  radicals in air samples, radiation dosimetry, redox activities of zeolite catalysts, and the metabolism of spin probes in cells and tissues.

### ENDOR Spectroscopy

Because of its close relationship with NMR spectroscopy, many of the applications involve a wide variety of magnetic nuclei. ENDOR spectroscopy not only yields information about static molecular properties, but it can provide an insight into molecular dynamics in a similar way to conventional ESR and NMR. ENDOR and ESR techniques have timescales of  $10^{-9}$ – $10^{-4}$  s, while that for NMR is  $10^{-5}$ – $10^{-1}$  s. Both ENDOR and ESR have been applied to studies of internal rotation, ring inversions, intramolecular electron transfer, or valence isomerizations.

These effects influence the linewidth if the timescale of the process is of the same order of magnitude as the timescale of the method.

Liquid crystals provide a useful approach to the investigation of quadrupolar nuclei since quadrupole interactions give rise to extra splittings in ENDOR spectroscopy.

ENDOR methods can be especially useful for investigating biological systems because powder-type spectra can yield isotropic and anisotropic coupling constants with a higher resolution and precision than can conventional ESR spectroscopy. Typical examples are the radical ions occurring as primary photoproducts in reaction centers of photosynthetic bacteria. Liquid-state ENDOR measurements have been made on biologically active organic species such as the vitamin quinones.

### ESR Imaging

ESR microscopy has been applied to a variety of problems including studies of defects in diamonds, diffusion of oxygen in model biological systems, radiometric dosimetry, and the distribution of radicals in a variety of solids. Examples include the *in situ* oxidation of coal, rock dating, and the investigation of the swelling of polymers using solvents containing spin probes.

Radiofrequency (and L-band) imagers are largely used for biological research to monitor the transport of spin-labeled reagents in small animals. Oximetry using solid particles also benefits from the spatial resolution derived from imaging techniques. These imagers clearly can be used for large specimens; for example, measuring the porosity of rocks using solutions of spin probes.

### Pulse Techniques

There are several obvious applications that are analogous to those encountered in NMR spectroscopy. Probably the most important of these is the measurement of relaxation times that are of the order of microseconds. In NMR, these times are of great structural value and lead to conclusions about molecular motion. No doubt these benefits will also apply to ESR as commercial pulse spectrometers become more widespread. If the relaxation times of two paramagnetic centers are sufficiently different, their spectra can be separated easily using the

echo-detected ESR method. When rapid reaction kinetics is being measured, information is also gained on transient phenomena such as chemically induced electron polarization.

ESEEM has been applied to the study of surface complexes, coordination of water in metmyoglobin, the structures of ligands in a copper protein, magnetic properties of electronic triplet states, and solitons in polyacetylene.

Pulsed ENDOR avoids some of the difficulties encountered with CW ENDOR in that the entire pulse sequence can usually be made short enough to exclude unwanted relaxation effects. This means that the pulsed ENDOR method can be used at any temperature, provided that an electron spin echo can be detected. There are a variety of pulse ENDOR techniques that have been applied to the investigation of free porphyrin bases and of nitrogen-14 nuclei in a disordered system.

### Introduction

The application of electron spin resonance (ESR) to biological studies started from the realization that free radicals play a very important role in enzymatic protein catalysis. In the 1950s Barry Commoner in the USA and Lev Blumenfeld in the USSR were the first to begin testing this hypothesis using ESR spectroscopy on tissue and cell preparations. Subsequent studies confirmed the crucial role of paramagnetic metal complexes for the enzymatic activity of biological materials. Two examples are afforded by the process of mitochondrial respiration and the kinetics of the photosynthetic electron transport chain in plants and bacteria. The paramagnetic centers involve flavin and semiquinone radicals, or short-lived cationic or anionic radical intermediates. In addition, Helmut Beinert in the USA discovered in the late 1950s the presence of stable paramagnetic iron–sulfur centers in frozen animal tissues and cell components. Geometrical information on tertiary protein structure can be obtained if ESR spectroscopy is used to measure the distances between two paramagnetic sites in a protein. Such sites may be native (iron–sulfur clusters or metal ions) or artificially incorporated by means of a paramagnetic label in a well-defined location of the protein. Driven by technological advances, the necessary labeling techniques and distance measurements using pulsed ESR and pulsed electron nuclear double resonance (ENDOR) have undergone very rapid progress in recent years.

In recent years, much interest has been focused on the detection of reactive oxygen species (ROS) and nitric oxide (NO) radicals in viable cell cultures and tissues. The spin trapping technique has proved to be very valuable, and its general characteristics have been described elsewhere in this encyclopedia. The complex biochemistry involved requires special techniques for spin trapping ROS and NO in biological materials. Such techniques form the content of the final sections.

Finally, spin labeling of proteins, ESR oximetry, and the use of spin probes for investigation of the structure of biomembranes are classic examples of biological ESR. These topics have been discussed elsewhere in this encyclopedia.

### Structure and Function of Metalloproteins

Enzymes can be considered as highly developed and selective catalysts that control much of the chemistry in living organisms. In nearly all cases, the crucial reaction steps involve a redox reaction mediated by a transition metal ion, for example at the heart of the enzyme. Such electron transfers affect the electronic configuration of the metal ion and the magnetic moment of the ion. Many, though not all, important enzymes have at least one paramagnetic charge state and may be observed in principle using ESR. The ESR spectrum of transition metal ions is remarkably sensitive to the so-called crystal field interactions with the atomic neighbors of the ion (spin–lattice interaction). Their outer electronic states consist of so called d-states, i.e., the five possible states characterized by an orbital angular momentum quantum number  $L=2$ . In an isolated atom, all five orbitals would have the same energy. This degeneracy is partially or completely lifted by the interaction with surrounding ligands and leads to distinct positions of the energy levels. In this way, tetrahedral, octahedral, tetragonal, or square planar surroundings may be easily distinguished. ESR spectra are particularly sensitive to violations of the structural symmetry, such as small distortions of the tetrahedral pyramid or loss of axial symmetry of the metal center. In addition, the ESR spectra may show hyperfine couplings between the electronic spins and the magnetic moments of nearby magnetic nuclei like nitrogen ( $I=1$ ), hydrogen ( $I=1/2$ ), or many transition metal ions like Cu ( $I=3/2$ ), Co ( $I=7/2$ ), or Mn ( $I=5/2$ ). Additional structural information may be obtained by isotopic substitution of natural nonmagnetic nuclei by magnetic isotopes like  $^{57}\text{Fe}$  ( $I=1/2$ , natural abundance 2.2%) or  $^{67}\text{Zn}$  ( $I=5/2$ , natural abundance 4%). A table of the most relevant paramagnetic metal ions may be found elsewhere in the encyclopedia.

### Distance Measurements in Biomolecules

In noncrystalline samples, ESR provides a convenient technique for estimating the distance between paramagnetic sites on a macromolecule. The spatial distance between the sites determines the strength of the spin–spin interaction, which may be experimentally determined using ESR. Such interactions may be

studied in a liquid or frozen solution, glasses, in porous matrices, and in amorphous or crystalline solids. At close distances, the spin–spin interactions are sufficiently strong to affect the shape of continuous wave (CW) ESR spectra. At larger separations these interactions are weak and better resolved using modern pulsed ESR spectroscopy methods like electron spin echo modulation (ESEEM) or pulsed electron–electron double resonance (ELDOR or PELDOR). ESR is very selective as it provides information on only those few sites that carry an electronic magnetic moment. It has proved to be very valuable for macromolecules that cannot be crystallized or that are too large for nuclear magnetic resonance investigations in solution. Although pulsed ESR requires cooling to low temperatures, it can be applied to fully functional proteins embedded in their natural matrix like a lipid cell membrane or attached to a coenzyme. It provides information on protein tertiary structure, conformational changes during enzymatic activity, and the dynamics of protein folding. The paramagnetic sites may be endogenous flavin or semiquinone radicals, cation or anion radical intermediates, or paramagnetic metal centers. Additionally, exogenous spins may be included by site-directed spin labeling. The 3-(methanesulfonylthiomethyl)-2,2,5,5-tetramethylpyrrolidin-1-yloxy spin label (also called methane–thiosulfonate) is a nitroxide that has proved to be particularly useful for selective labeling of cysteine residues. It attaches to the protein backbone via a rigid disulfide bridge, which makes the orientation and mobility of the label reflect those of the backbone itself.

The spin–spin interactions are caused by either dipolar magnetic coupling between the spins or electronic exchange interaction due to orbital overlap between the two unpaired electrons involved. Such electronic exchange may be direct or mediated through hydrogen bonds or bridging ligands between paramagnetic metal centers. In continuous wave ESR, the coupling strength is best determined via the intensity of the so-called half-field transition, which occurs near half the magnetic field for the usual single quantum transitions. This double quantum transition becomes weakly allowed due to the anisotropic part of the spin–spin interaction (dipolar interaction and anisotropic exchange). The practical experimental range extends to distances up to  $\sim 12$  Å for continuous wave ESR and up to 30 Å for pulsed excitation of this double quantum coherence (DQC). Far longer distances are accessible by specialized pulsed ESR methods. Particularly useful are double frequency resonance techniques where two different spin transitions are successively excited by pulse sequences with two microwave frequencies. The

**Table 1** Selection from ESR methods to determine the distance between paramagnetic sites. The acronyms are explained in the text

<i>Technique</i>		<i>Range (Å)</i>	<i>No. of frequencies used</i>
Spectral simulation	CW	4–20	1
Intensity of half-field transition	CW	4–12	1
Intensity of half-field transition	Pulsed	12–25	1
DQC	Pulsed	20–30	1
DEER	Pulsed	15–70	2
PELDOR	Pulsed	15–130	2

coherent excitation of two different microwave transitions provides a high selectivity that allows the determination of even very weak coupling between distant spins. The basic PELDOR experiment is based on a three-pulse sequence but suffers from experimental limitations like ‘blind spots’ and ‘dead time’. These problems may be reduced in the more sophisticated four-pulse double electron–electron resonance (DEER) spectroscopy.

The most commonly used ESR methods for distance measurement are listed in Table 1.

### ESR-Detectable Endogenous Paramagnetic Centers in Animal Tissues, Cells, and Bacteria

The majority of endogenous paramagnetic centers detected in animal cells and tissues arise in electron transport chains (ETCs) of mitochondria. They comprise heme or nonheme iron-containing proteins (cytochromes and iron–sulfur proteins, respectively),  $\text{Cu}^{2+}$ -containing proteins, protein-based radical centers (flavine mononucleotide or flavine adenine nucleotides) as well as certain radical intermediates of low molecular weight (ubiquinones). Due to intensive spin–lattice relaxation, the ESR spectra of iron-containing protein components of ETC can be recorded only at cryogenic temperatures in the range 4–80 K. Microwave power saturation of the ESR signals should be avoided at such low temperatures.

Figure 1 shows the complex ESR spectra from isolated cardiac mitochondria. They appear as a superposition of spectra from various paramagnetic components of the mitochondrial ETC. They are mainly iron–sulfur centers, denoted as N1, N2, N3 + 4 (located in complex I, NADH–ubiquinone oxidoreductase), S1 (complex II, succinate–ubiquinone oxidoreductase), and the Rieske iron–sulfur protein (complex III, ubihydroquinone–cytochrome C oxidoreductase). The positions of the components

**Figure 1** EPR spectra of electron transport particles (ETPs) from heart mitochondria from titration with NADH. (A) ETPs treated as other samples except that no reductant was added; (B)–(E) reduced with increased dose of NADH. (i.e., the  $g$ -tensor values) are shown in **Figures 1** and **3**. Similar spectra are characteristic of various isolated animal tissues. As shown in **Figures 2** and **3**, the shape of the spectrum depends on the redox state of the paramagnetic centers. Full reduction of the mitochondrial ETC components is obtained upon depletion of oxygen in tissue. In the oxidized state, the ESR spectra appear as superpositions from cytochromes, the copper center in cytochrome oxidase, and a high-potential iron–sulfur center, S3 (complex II). An additional signal arises from the iron–sulfur

**Figure 2** EPR spectra of whole pigeon heart at different reductive states of the electron carriers (the extent of reduction increases from A to C). cluster of mitochondrial aconitase, the enzyme from the Krebs cycle.

The ESR spectra also give valuable information on pathologies like cancer. **Figure 4** shows that the iron–sulfur signals from hepatoma mitochondria in Morris rats are correlated with the mitochondrial respiratory activity. In the slow-growing hepatoma-16 tumors, the iron–sulfur signals from reduced nicotinamide adenine dinucleotide (NADH) dehydrogenase are smaller than from surrounding nonaffected liver tissue or liver from healthy rats. In the rapidly growing hepatoma-7777 cells, the ESR signals of iron–sulfur centers are even more diminished. The data show that the abnormal metabolic characteristics of some tumors are related to specific defects in the iron–sulfur components of the ETC.

Recent ESR data suggest that the final step of proton translocation in complex I involves an endoenergetic electronic disproportionation in the ubisemiquinone pair. If tightly coupled and functioning bovine heart submitochondrial particles are snap

frozen in the presence of an NADH substrate, strong ESR signals at  $g=2.00$  show that one ubisemiquinone of this pair is in a radical state (spectra shown in Figure 5). It undergoes fast spin-spin relaxation

due to interaction with the iron-sulfur center, N2, located at a distance of only  $10 \text{ \AA}$ . This ubisemiquinone signal was not detected in uncoupled submitochondrial particles. The data suggest that energy

**Figure 5** EPR spectra of uncoupled (A) and tightly coupled (B) submitochondrial particles during steady-state NADH oxidation. Recordings were made with microwave power 2 mW and temperature 16 K. (Reproduced with permission from Vinogradov A *et al.* (1995) Energy-dependent Complex I-associated ubiquinones in submitochondrial particles. *FEBS Letters* 370: 83–87.)

transduction in mitochondria requires the participation of bound ubiquinones as well as the iron-sulfur center N2.

Analysis of these mitochondrial ESR spectra sheds light on the nature, redox state, and quantity of the ETC components. This has been very helpful in understanding the redox behavior of enzymatic centers and in deducing their orientation in mitochondrial membranes. It should be kept in mind that the ESR spectra reflect the ETC components in the frozen state. As such, the spin and redox states of the paramagnetic centers may differ from those of the active enzyme at a physiological temperature.

Oxidized cytochrome,  $P_{450}$ , is the terminal component of the microsomal ETC. Its  $g$ -values at  $g = 2.42$ ,  $2.25$ , and  $1.91$  are easily distinguishable from those of components in the mitochondrial ETC. Spectra from this enzyme are often detected in

**Figure 6** ESR spectra of liver tissue from mice at 77 K: (A) control animal on normal diet; (B) mouse on drinking water with 0.3% nitrite for 7 days. The nitrite consumption induces formation of dinitrosyl-iron (DNIC 0.03) and nitrosyl-heme complexes, at  $g = 1.98$ . isolated liver and kidney tissue at temperatures below 100 K (**Figure 6**). The redox processes in the microsomal ETC ensure detoxication of many xenobiotics as well as the biosynthesis and biodegradation of endogenous compounds like steroids or fatty acids. The detoxication defense of many bacteria, insects, fishes, yeasts, and plants involves a wide range of cytochromes. Like cytochrome  $P_{450}$ , these cytochromes have paramagnetic charge states. ESR spectroscopy has proved to be very useful for studying the catalytic cycle of this class of enzymes. A particular success was the detection of the so-called Compound 1, a highly redox-active intermediate porphyrin radical-cation- $\text{Fe(IV)}=\text{O}$  complex.

Paramagnetic centers are found in many specific enzymes and proteins that function in animal tissues and bacteria (oxygenases, sulfite or nitrite reductases, xanthine oxidase, nitrogenase, etc.) besides mitochondria and microsomes. The catalytic site can include Mo, Cu, Co, Ni, Mn, and other metal ions. However heme- and iron-sulfur centers constitute the majority of the paramagnetic centers found outside the mitochondria.

In recent years, the interest in the physiological role of nitric oxide radicals has greatly stimulated the investigation of iron–nitrosyl complexes. The generation of nitric oxide in mammalian tissues, cultured cells, or bacteria is usually accompanied by the formation of paramagnetic mononitrosyl–heme iron complexes and dinitrosyl–nonheme iron complexes (DNICs). The respective ESR signals of the complexes are shown in **Figure 6**. Nitric oxide is recognized now as a signaling and regulatory radical that influences diverse physiological and biochemical processes. In biosystems, it is generated either enzymatically by NO synthases or nonenzymatically (mainly from nitrite). A possible physiological role of the paramagnetic nitrosyl–iron complexes is now being hotly debated and investigated.

Various forms of DNIC may be distinguished according to the structure of the thiolate group that ligates to the central iron atom. The preliminary results suggest that DNICs may be implicated in the redox chemistry of *S*-nitrosothiols. The latter are known to have antioxidant as well as signaling functions in cells and tissues. Recently DNICs have been found in plant leaves upon supplementation of NO from an exogenous source or generated endogenously from nitrite. It is reasonable to suggest that the formation of DNICs from nonheme iron prevents iron precipitation in the form of hydroxide complexes. This would increase the iron availability for various intracellular components, particularly for chloroplasts.

### ESR-Detectable Endogenous Paramagnetic Centers in Photosystems of Plants

ESR spectroscopy has been very useful in studying the photosynthetic function in plants and bacterial photosystems. It had been known for a long time that illumination causes free radical ESR signals in photosynthetic systems, and subsequently the importance of nonheme iron and then manganese complexes was discovered. The photosynthetic activity of plants is based on two supramolecular assemblies, photosystems I and II, which act in tandem. Each photosystem consists of a light harvesting antenna structure containing chlorophyll dye molecules, and a cascade of electron acceptors that act in succession as an electron transport chain for charge separation.

The ESR signals from the photosystems may be observed at cryogenic temperatures and depend sensitively on the state of illumination. **Figure 7** shows the spectra of photosystem I from spinach chloroplasts. Under steady illumination, they appear as a superposition of an intense  $g = 2.00$  free radical line

**Figure 7** Photoreduction of a bound Fe–S center in intact spinach chloroplasts after illumination at 77 K. Recordings were made at 10 K. (Reproduced with permission from Malkin R and Bearden A (1971) Primary reactions of photosystem: photoreduction of a bound ferredoxin at low temperature as detected by ESR spectroscopy. *Proceedings of the National Academy of Sciences of the USA* 68: 16–19.)

from oxidized pigment  $P700^+$  and an anisotropic ESR signal at  $g$ -values of 2.05, 1.94, and 1.86 assigned to a reduced Fe–S center. A quantitative comparison of the  $P700^+$  content and paramagnetic Fe–S center, as well as a comparison of their kinetics characteristics at temperatures 10–100 K, has shown that photosystem I has a good correlation between  $P700$  oxidation and the ESR intensity from the Fe–S center. This center turned out to be the secondary electron acceptor from the electron transport chain. The nature of the primary quinone–iron acceptor is revealed using ESR if the electronic pathway to the secondary acceptor is blocked. In the reduced state, this so-called X center has a broad spectrum with  $g = 1.78$ , 1.88, and 2.08.

Photoinduced oxidation of water into dioxygen is the central step in photosynthesis. It is carried out through a characteristic tetranuclear manganese cluster in photosystem II. This cluster is the active site for water oxidation by formation of the so-called oxygen-evolving complex (OEC). Photosynthetic oxidation of water is a highly complex mechanism involving a sequence of five intermediate states,  $S_i$ . It has been proved that the first intermediates,  $S_0$ – $S_3$ , of the Mn–OEC donor complex are sufficiently stable to be detected in frozen samples using ESR. For example, **Figure 8** shows the spectrum of the  $S_2$  state. The signal is mainly accepted to arise from a  $S = 1/2$

**Figure 8** EPR spectra associated with the oxygen-evolving center in photosystem II preparations: the multiline EPR signal and the signal at  $g = 4.1$  (top panel) from the preparation in the  $S_2$  state (illumination at 195 K); EPR signal (shown at the bottom) produced by continuous illumination of a sample at 200 K in the presence of  $20 \text{ mmol l}^{-1}$ , 20 mM fluoride. Recordings were made at 10 K. A narrow ESR line from a spurious free radical near  $g = 2.0$  was removed from the spectra. (Reproduced with permission from Yachandra V, Sauer K, and Klein M (1996) Manganese cluster in photosynthesis: Where plants oxidize water to dioxygen. *Chemical Reviews* 96: 2927–2950.)

antiferromagnetically exchange-coupled  $\text{Mn}_4(\text{III}, \text{IV}_3)$  cluster. A multiline structure is located near  $g = 2.00$  and shows well-resolved hyperfine couplings from the manganese nuclei. The additional low-field signal at  $g = 4.1$  is suggested to arise from some clusters existing in a high-spin  $S = 3/2$  or  $S = 5/2$  electron configuration. The  $g = 4.1$  signal can also be formed through infrared illumination of the  $S = 1/2$  state at 65 K. It is also observed in photosystem II upon exposure to  $\text{F}^-$  anions. Such samples lose the multiline structure near  $g = 2.00$  as well as the capacity to generate  $\text{O}_2$ .

Interestingly, the halide anion  $\text{Cl}^-$  is an essential cofactor for  $\text{O}_2$  production through photosystem II. The anion may be replaced by  $\text{Br}^-$  with full retention of activity. Moreover, either  $\text{Cl}^-$  or  $\text{Br}^-$  is required for the multiline structure near  $g = 2.00$ , which is characteristic of the  $S_2$  state. It strongly suggests that the halide anion is a ligand of the Mn atoms in the cluster, but up to now attempts to detect

**Figure 9** ESR spectra of free tyrosyl radical TyrD photogenerated in Mn-depleted photosystem II at 4 K (A) and warming to 200 K (B). The spectral change near 0.3362 T is attributed to a thermally activated deprotonation of the  $\text{Y}_D^+$  radical. (Reproduced with permission from Faller P, Goussias C, Rutherford AW, and Un S (2003) Resolving intermediates in biological proton-coupled electron transfer: A tyrosyl radical prior to proton movement. *Proceedings of the National Academy of Sciences of the USA* 100: 8732–8735.)

the hyperfine interaction from the halide ion have failed.

The Mn cluster is not directly photoactivated itself but via an indirect redox process involving a tyrosine intermediate. Upon photoactivation of the primary donor in photosystem II, the excited electron is injected into the electron transport chain and removed. The oxidized primary donor,  $\text{P680}^+$ , receives an electron from a nearby tyrosine  $\text{Y}_Z$ . The resulting  $\text{Y}_Z^+$  radical intermediate oxidizes the tetranuclear Mn–OEC to a high valence state that is capable of oxidizing water. This short-lived  $\text{Y}_Z^+$  radical intermediate has ms lifetime and has been studied with pulsed ESR and optical spectroscopy. In addition, illuminated photosystem II contains a long lived  $\text{Y}_D^+$  tyrosyl radical, which is stable at cryogenic temperatures. The ESR spectra reveal a thermal relaxation of the molecular structure around this  $\text{Y}_D^+$  radical at 80 K (see Figure 9). The spectral changes were attributed to a thermally induced deprotonation of the  $\text{Y}_D^+$  cation.

## Spin Trapping of Nitric Oxide

NO radicals are paramagnetic with a degenerate ground electronic state, which precludes direct ESR detection except at cryogenic temperatures in the

frozen state. When bound with various protein amino acid residues, it forms paramagnetic centers that may be observed even at room temperature. The ESR spectra resemble those from stable nitroxyl radicals like 2,2,6,6-tetramethyl piperidino oxy nitroxide (TEMPO). As these centers are susceptible to oxidation by superoxide, their concentrations usually remain below the detection threshold in biosystems. Spin trapping of NO molecules provides a good alternative. Various derivatives of dithiocarbamate ligands are known to enhance considerably the affinity of ferrous ions for NO molecules. The straightforward binding of NO to the Fe(II)–(dithiocarbamate)<sub>2</sub> complex is often referred to as a trapping reaction of NO. The adduct is a paramagnetic mononitrosyl-iron complex (MNIC) with dithiocarbamate ligands that can be detected and evaluated using ESR spectroscopy even at ambient temperature.

Figure 10 shows the spectra of MNICs in the frozen and liquid solution states, respectively. The triplet structure is caused by hyperfine interaction of the unpaired electron with the nitrogen nucleus ( $I=1$ ) of the NO ligand. The moderate magnitude of this hyperfine splitting demonstrates that the unpaired electron is largely transferred from the NO to the iron atom, which must have a formal monovalent

redox state of Fe(I). Depending on the hydrophobicity of the dithiocarbamate ligands, the MNIC complexes localize preferably in either the hydrophobic or the hydrophilic compartments of cells of tissues. Widely used dithiocarbamates include diethyldithiocarbamate (DETC) and *N*-methyl-D-glucamine dithiocarbamate (MGD), which give rise to hydrophobic and hydrophilic MNICs, respectively. After supplementation of free iron and dithiocarbamate ligands, such MNICs are detectable in many biosystems using ESR spectroscopy, from cultured viable mammalian cells and tissues to living plants (Figure 11). The NO trapping and MNIC formation proceeds *in vivo*, whereas the actual ESR detection and quantification of MNICs is usually carried out *ex vivo*. Recent advances in sensitivity have even allowed MNIC detection in small living mammals. In combination with ESR imaging, MNIC even allows NO tomography revealing the distribution of MNICs in the body of a small animal.

ESR spectroscopy has provided the first unequivocal proof that NO synthesis from L-arginine using NOS enzymes is the only relevant source of NO in mammals: MNIC formation can be prevented by infusion of NOS inhibitors. In addition, isotopic labeling of L-arginine with <sup>15</sup>N ( $I=1/2$ ) isotopes leads to the formation of MNICs with a doublet structure instead of the usual nitroxide triplets obtained with the natural <sup>14</sup>N isotope (Figure 11). In this context, it should be mentioned that modest quantities of NO may also be released from nitrite via nonenzymatic pathways under conditions of acidosis.

It is noteworthy that Fe–dithiocarbamate traps are normally used in the millimolar range. As such, MNIC formation will provide the dominant reaction pathway for endogenous NO molecules under normal physiological conditions. In particular, we can neglect the alternative pathway involving superoxide anions that is present in living systems at a concentration of not more than a few micromoles. Nevertheless, as will be discussed below, the presence of superoxide has a big effect on the MNIC lifetime. Experimental MNIC spectra obtained in tissues usually have to be corrected for the presence of an additional broad background caused by paramagnetic Cu(II)–DETC complexes. DETC is a sufficiently good chelator to scavenge spurious free copper and even extract Cu(II) ions from certain endogenous enzymes like superoxide dismutase (SOD).

The interpretation of NO trapping experiments using Fe–dithiocarbamate complexes is particularly complicated by the redox activity of both Fe–dithiocarbamate complexes and their nitrosyl adducts. The Fe(II)–dithiocarbamate complexes are easily

**Figure 10** EPR spectra of MNIC–MGD complexes in aqueous solution, including <sup>56</sup>Fe (A and B) or <sup>57</sup>Fe (C and D). Recordings were made at 77 K (A and C) or ambient temperature (B and D). Isotopic substitution of <sup>56</sup>Fe ( $I=0$ ) with <sup>57</sup>Fe ( $I=1/2$ ) results in changes in the signal shape that are due to the manifestation of an additional HFS induced by interaction of the unpaired electron with the <sup>57</sup>Fe nucleus ( $I=1/2$ ). EPR spectra from MNIC–DETC. **Table 2** Spectroscopic properties of iron(II) and iron(III)-MGD complexes in aqueous solutions<sup>a</sup>

Iron-carbamate complex	Absorption wavelength (nm)	Extinction coefficient ( $\text{l mol}^{-1}$ )	Color
Fe(II)-MGD	—	—	Clear, diamagnetic
Fe(III)-MGD	340, 385, 520	20 000, 15 000, 3 000	Orange-brown, paramagnetic ( $S=3/2$ )
NO-Fe(II)-MGD	314, 368, 450	18 000, 12 500, 5 600	Deep green, paramagnetic ( $S=1/2$ )
NO-Fe(III)-MGD	No peaks	~20 000 at 350 nm	Yellow, diamagnetic

<sup>a</sup>Data adapted with permission from Vanin A *et al.* (2000) Redox properties of iron-dithiocarbamates and their nitrosyl derivatives: Implications for their use as traps of nitric oxide in biological systems. *Biochimica Biophysica Acta* 1474: 365-377.

oxidized to Fe(III)-dithiocarbamate complexes by dissolved oxygen. In an aqueous solution, the rate constant of the reaction for Fe(II)-MGD complexes was determined as  $5 \times 10^5 \text{ l mol}^{-1} \text{ s}^{-1}$  at ambient temperature. Superoxide radicals react considerably faster with a rate of  $3 \times 10^7 \text{ l mol}^{-1} \text{ s}^{-1}$ . The Fe(III)-(dithiocarbamate) $_3$  complexes can also bind NO molecules, which results in the formation of diamagnetic iron(III) nitrosyl derivatives. However, the latter are rather unstable and slowly transform into paramagnetic MNIC-dithiocarbamate under anaerobic

conditions. This transformation may be accelerated by addition of reducing agents like ascorbate. Interestingly, the presence of the NO ligand seems to facilitate this reduction step as the reduction of the iron from the Iron(III) to the Iron(II) state is considerably slower in the absence of NO. The redox conversion may be followed spectroscopically using ESR as well as optical absorption as the redox state and the presence of the NO ligand strongly affect the color of the iron complex. Table 2 lists the optical and ESR properties.

We stress that ESR spectroscopy only detects the paramagnetic versions of MNIC. As such, the ESR intensity may only reflect the NO levels in tissues or biomaterials if all the iron is reduced to the Iron (II) state. Three pathways for this transformation are known in biomaterials. The first is straightforward reduction of diamagnetic MNICs by endogenous reducing agents like glutathione and ascorbate. Second is a mechanism of reductive nitrosylation similar to that proposed for nitrosyl ferrihemoproteins, where the NO ligand reduces the iron to the ferrous state, followed by release of  $\text{NO}^+$  from the complex. Nevertheless, it should be kept in mind that these mechanisms do not ensure complete reduction of all complexes to the iron(II) state.

An additional problem concerns the stability of paramagnetic MNICs in biomaterials. It has recently been discovered that paramagnetic MNICs react rapidly with superoxide and peroxynitrite. The reaction products are ESR-silent nitroso complexes. In other words, the adducts are formed but do not survive. This complication can be partially redressed by the so-called ABC method. Its basic idea is to overwhelm these alternative pathways by bolus injection of a known quantity of exogenous MNIC to a cultured cells or animal tissue. It acts as a very efficient scavenger of superoxide anions and peroxynitrite, so that endogenously formed MNIC adducts survive. This experiment is repeated in the presence of a NO synthase inhibitor. The endogenous NO levels are estimated from the difference between these two experiments: first experiment =  $A + B - C$ , second experiment =  $A - C$ , where  $A$  is the signal from the exogenous MNIC bolus injection and  $B$  is the signal due to endogenous NO production. The quantity  $C$  accounts for the endogenous MNIC adducts transformed into the ESR-silent state by superoxide and/or peroxynitrite.

Figure 12 illustrates the advantage of the ABC method over the 'conventional' method in cultured endothelial BEND3 cells. The ABC method allows detection of a larger fraction of endogenously produced NO. As such, it gives a better representation of NO levels in biomaterials, tissues, and living systems. Still, we cannot exclude the possibility that an unknown fraction of NO ends up in ESR-silent nitroso compounds.

Organic spin traps are also used for NO detection in chemical and biological systems. For example, 2,5-dimethylhexadiene, when introduced into degassed organic solutions of NO, yields a three-line ESR signal, tentatively assigned to 2,2,5,5-tetramethyl-1-pyrroloxy. Paramagnetic nitronyl nitroxides change their ESR spectrum when they react with NO to form a paramagnetic imino nitroxide adduct.

**Figure 12** EPR spectra of MNIC-DETC complexes formed in suspensions of viable endothelial cells. (A) In the absence of NOS inhibitor, *N*-nitro-L-arginine (NLA); Endogenous and exogenous MNIC-DETC make contributions to the signal. (B) With  $1 \text{ mmol l}^{-1}$  NLA. Only exogenous MNIC-DETC makes a contribution to the signal. (C) Computed difference (A-B), showing the endogenous MNIC-DETC formed NO synthesis. (D) Reference spectrum showing MNIC-DETC complexes formed endogenously by conventional NO trapping. Spectra were recorded at 77 K. The relative gain settings are shown at the right side of the spectra ABC method. (Reproduced with permission from Vanin *et al.* (2001) Antioxidant capacity of mononitrosyl-iron-dithiocarbamate complexes: Implications for NO trapping. *Free Radical Biology and Medicine* 30: 813–824.)

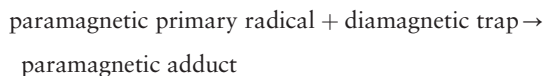

For example, PTIO or carboxy-(2-(*p*-carboxy)phenyl-4,4,5,5-tetramethylimidazoline 3-oxide-1-oxyl) reacts efficiently with NO to form paramagnetic carboxy-(2-(*p*-carboxy)phenyl-4,4,5,5-tetramethylimidazoline 3-oxide). However, in viable cells and tissues, such adducts are easily transformed into diamagnetic hydroxylamines. This property severely limits the ESR application of these traps in bioassays. Potentially valuable information may be obtained from the class of fluorescent cheletropic traps. These have weak red fluorescence and react with NO to form nonfluorescent paramagnetic adducts. The latter are rapidly transformed into a diamagnetic hydroxylamine with strong blue fluorescence, which is easily observable using fluorescence microscopes and spectrometers. Nevertheless, iron-dithiocarbamate complexes form the basis of the most valuable and reliable ESR technique for detecting NO in living tissues.

## Spin Trapping of Oxygen Radicals

Singlet oxygen, triplet oxygen, ozone, superoxide anions and the hydroxyl radicals are all fairly reactive oxygen species. Singlet oxygen is diamagnetic and unobservable using ESR, whereas the remaining

species are paramagnetic. They cannot be observed directly using ESR due to line broadening or the short lifetimes of the species. In biological materials, ozone does not occur in significant quantities and will not be considered further. Superoxide and hydroxyl radicals have been recognized as major and inseparable agents in the development of physiological pathologies. In biological research, these radicals always appear in the company of the nonradical hydrogen peroxide, to which they are linked via a complex series of chemical reactions (dismutation and iron-mediated Fenton chemistry are discussed elsewhere). Evolution has developed elaborate enzymatic defenses to reduce the *in vivo* levels of superoxide and hydrogen peroxide, in the form of superoxide dismutase and catalase, respectively. Nevertheless, minute quantities of oxygen radicals may escape the defenses and contribute to undesirable oxidative stress and oxygen toxicity.

The superoxide anion  $O_2^-$  is modestly reactive when compared with most other radicals but still is a stronger one-electron reductant and oxidant than  $O_2$  itself. This  $S = 1/2$  radical can be observed using ESR only in exceptional cases where the spin relaxation is reduced sufficiently. In biological systems, its concentration remains too low and the linewidth too broad for observation. In the late 1960s, nitroso and nitron compounds were introduced as spin trapping agents to detect superoxide radicals. The traps are diamagnetic, but their reaction with the primary radical leads to the formation of a more stable paramagnetic reaction product in the form of a nitroxide (adduct in spin trapping terminology):

The ideal spin trap should be stable, with rigorously stable adducts. The adduct spectra should depend distinctively on the primary radical to allow unambiguous identification of the latter. In reality, the adducts are susceptible to hydroxylation into a diamagnetic hydroxylamine that is ESR silent. This hydroxylation is a serious complication for radical detection in biological systems, particularly in blood samples.

Compared with nitrones, nitroso compounds like 2-methyl-2-nitrosopropane (MNP) incorporate the superoxide radical closer to the nitroxide center. Therefore, the adduct spectra provide more information on the nature of the primary radical, making its identification easier. But nitroso traps and their adducts are more susceptible to thermal, photochemical, and hydroxylative degradation as well as -ene addition. They have limited solubility and tend to

dimerize, leaving only a small concentration of the monomer, which alone is capable of the trapping reaction. Some traps like MNP are sufficiently volatile to be lost from solutions through degassing via nitrogen bubbling.

Wider applications include nitron spin traps, which are light insensitive, nontoxic, and lead to reasonably robust adducts. The adduct spectra do not distinguish between different primary radicals as these get inserted at the  $\beta$ -position further away from the nitroxide center. Phenyl-*tert*-butylnitron (PBN) and 5,5-dimethylpyrroline (DMPO) are most widely used for superoxide detection in hydrophobic and hydrophilic compartments of biological samples, respectively. DMPO is the standard of choice for application in cell cultures as it readily crosses cell membranes. The spectrum of its superoxide adduct, DMPO-OOH, is shown in Figure 13. The interpretation of the trapping experiments is complicated by the poor stability of DMPO-OOH,

**Figure 13** Room temperature spectra of DMPO-OOH adduct (top) and DMPO-OH adduct (bottom) in liquid solution.

**Figure 14** Room temperature spectra of DEPMPO-OOH adduct (top) and DEPMPO-OH adduct (bottom) in liquid solution.

which spontaneously dismutates into the very same DMPO-OH adduct that results from the trapping of the hydroxyl radical. Usually, additional experiments in the presence of effective superoxide scavengers like SOD are needed before the primary radical can be identified unambiguously. It should be noted that the rates of the trapping reaction depend sensitively on the pH. For DMPO, the reaction rate with protonated superoxide exceeds that of the superoxide anion by nearly three orders of magnitude.

The recently developed nitron 5-diethoxyphosphoryl-5-methyl-1-pyrroline-*N*-oxide (DEPMPO) leads to adducts with better stability. Additionally, its decomposition does not lead to potentially misleading DEPMPO-OH adducts. This important advantage has a price: the trap cannot penetrate cell membranes, and the ESR spectra appear as the spectral superposition of two isomers in varying concentrations (Figure 14).

Usually, spin traps exhibit fairly small reaction rates with superoxide, of the order of  $1\text{--}20\text{ l mol}^{-1}\text{ s}^{-1}$  at room temperature. Therefore, fairly long incubation times ( $\sim 1\text{--}30\text{ min}$ ) and high trap concentrations ( $10\text{--}50\text{ mmol l}^{-1}$ ) are required to accumulate sufficient adducts and to capture a substantial fraction of the superoxide in the assay. Recently, traps with higher reaction rates have become available that can be applied at high micromolar concentrations. For

blood, the highly reactive 1-hydroxy-3-carboxy-2,2,5,5-tetramethylpyrrolidine (CP-H) has been applied, in spite of a serious susceptibility to artificial adduct formation via secondary pathways (spurious metal ions, peroxyxynitrite, nonoxygen radicals).

In contrast to superoxide, the hydroxyl radical is one of the most reactive substances known. It reacts rapidly with nearly every substance at rates limited only by the time needed to approach its reagent diffusively. As such, it may become difficult to detect by spin trapping in biological materials, where many alternative reaction pathways compete with the trapping reaction. DMPO has proved to be useful in biological systems because the stability of the DMPO-OH adduct comfortably exceeds that of the adducts formed with PBN of  $\alpha$ -(4-pyridyl 1-oxide)-*N*-*tert*-butylnitron (4-POBN) spin traps.

## Introduction

Many substances exist in solution as electrically charged species. Once ionized, cations (+) or anions (−) can be separated in an electrical field where they will migrate toward the cathode or anode depending on their charge (Figure 1). This is the basis of electrophoresis (Gr. 'electro': electric, and 'phoresis': to carry).

The rate at which ions move toward the attracting electrode is dependent on the balance between the

impelling force of the electric field on the charged ion and the frictional and electrostatic retarding effects (i.e., the drag) between the sample and the surrounding medium. The degree of the drag depends on the size and shape of the molecule and on the viscosity of the matrix. An estimate of the velocity of a molecule in an electric field, in a solution, is given by the following equation:

$$v = Eq/d6\pi r\eta$$

where  $v$  is the velocity at which the molecule is moving,  $E$  the electric field,  $q$  the net charge on the molecule,  $d$  the distance between the electrodes,  $r$  the radius of the molecule, and  $\eta$  the solution viscosity.

The movement of an ion is proportional to its charge and the electric field, and inversely proportional to its size and the viscosity of the surrounding medium.

## History

The first investigations with electrophoresis were carried out by Lodge in 1886, and were performed using a curved tube filled with jelly and an aqueous solution. Acidic and basic ions were added at the positive and negative ends of the tube and a current was applied, this caused the jelly/solution boundary to move giving an indication of the net ion migration in the system. Linder and Picton in 1896 replaced the jelly with a colored colloidal solution and observed the migration of inorganic compounds and hemoglobin. This method became known as moving boundary or 'free' electrophoresis. When

**Figure 1** General theory of electrophoresis. Many substances exist in solution as electrically charged species. Ions can be separated in an electrical field where the speed and direction of movement depends on their charge.

electrophoresis is conducted in a solution the minimal frictional resistance allows rapid migration of sample components. The technique was used mainly for separating components in biological fluids and also in water purification.

It was not until the work of Tiselius in the 1930s that the potential of electrophoresis as a biochemical tool was realized. Tiselius developed the use of electrophoresis for separating proteins in suspension on the basis of their charge. He optimized the geometry and temperature of the system in an apparatus known as the Tiselius 'moving boundary' system. Detection of the separated components was carried out by detecting concentration changes in optical refraction.

There were still limitations to this method as relatively large samples were required and complete separation was impossible due to boundary issues in the solution. These problems were solved with the use of stable media in which components of a sample migrate as distinct zones, which can then be detected with suitable equipment. This method is termed zone electrophoresis. In 1937, Konig developed a method using paper as the stable medium. Disadvantages associated with paper (dealt with below) led to the development of methods using other media, e.g., Smithies (1955) using starch gel and Kohn (1957) using cellulose acetate. In 1959, Ornstein and Davies and, independently, Raymond and Weintraub, and also Hjerten (1960), developed methods using polyacrylamide gel, where separation is based on both electrophoretic mobility and sieving effects.

Svensson (1961) and subsequently Vesterberg (1969) developed the important technique of isoelectric focusing (IEF). This method exploits the principles of moving boundary electrophoresis. Components are separated according to their pI by the use of carrier ampholytes in the supporting medium. An ampholyte is a compound that can have basic and acidic properties, such as amino acids. The migration of ampholytes is therefore pH dependent. This method has been combined with gel electrophoresis to form the powerful tool of two-dimensional gel electrophoresis pioneered by O'Farrell in 1975.

The next important development in electrophoresis occurred in the 1970s with the emergence of capillary electrophoresis (CE). This technique involves the application of high voltages across buffer-filled capillaries to achieve separations. Until this time electrophoresis equipment offered a low level of automation, long analysis times, with detection only possible by postseparation visualization. Conducting electrophoresis in capillaries overcame these problems with automated analytical equipment, fast analysis times, and online detection of separated

components. Jorgenson and Lukacs, in the 1980s, enhanced this technique and in recent times CE has accelerated the completion of the Human Genome Project.

## General Considerations in Electrophoresis

Several important parameters influence the behavior of a sample being electrophoresed. The electric field is obviously important. Characteristics of the charged molecule or ion itself can affect its migration rate. For example, the higher the net charge on a molecule the more quickly it will move. Whereas the larger the molecule the more slowly it tends to migrate due to increased frictional and electrostatic forces. The shape of a molecule can influence its migration rate since molecules of similar mass and net charge may migrate at different rates due to differential effects of frictional and electrostatic forces.

The choice of buffer is very important as it stabilizes the pH of the sample and the supporting medium. It should also act as an acceptable electrolyte. The buffer is generally chosen to ensure that the sample components do not bind to it altering their rate of migration. In some cases, however, this interaction is desirable. For example, borate buffers are used to separate carbohydrates as they form charged complexes with them. With high ionic strength buffers the proportion of the current carried by the buffer is high and the proportion carried by the sample is relatively lower, reducing the rate of migration. Heat production also increases. Conversely, at low ionic strengths the proportion of current carried by the sample is higher and the migration rate is faster. A low ionic strength buffer reduces the overall current and results in less heat production, but diffusion and resulting loss of resolution are higher. The pH of the buffer is very important when separating organic compounds as it influences the degree of ionization and therefore migration will be pH dependent. When separating fully ionized inorganic compounds the pH of the buffer will have little effect. The temperature of the system can affect the migration of ions, with an increase in temperature increasing velocity.

The support medium used to carry out the separation will have an effect on the migration of components due to adsorption, electroendosmosis, or molecular sieving. Adsorption occurs when the sample sticks to the support medium (such as to the cellulose hydroxyl groups of cellulose paper) giving a characteristic comet shape to the separation. Adsorption reduces both the rate and resolution of the

separation. Electroendosmosis is a phenomenon that occurs when the surface of the supporting medium becomes negatively charged in contact with water in the buffer solution. This can result in a change in mobility of charged molecules and is an important consideration when the isoelectric points of compounds are required. Allowance can be made for this effect by measuring the migration of neutral compounds in the same system. Molecular sieving occurs in gel media where the movement of large molecules is hindered by the gel matrix. Decreasing the pore size of the gel will decrease the mobility of the larger molecules. Consideration of all of these properties will determine the type of support medium to be used for particular samples to be separated.

## General Techniques and Applications

Separation of samples using electrophoresis can be useful both for analysis and as a preparative tool. The sample and purpose of the separation will determine which electrophoresis protocol will be the most useful. The following section is a brief overview of some of the techniques and media available and their applications. This is by no means a comprehensive list and readers are referred to the references at the end of this article for more detailed information.

### Paper Electrophoresis (Low Voltage)

Low-voltage paper electrophoresis is the simplest and cheapest form of electrophoresis. A strip of commercially available chromatography paper is soaked in buffer and placed with one end in each buffer reservoir (connecting wicks may be used). It is important that the paper is saturated with the buffer since it is the buffer that conducts the majority of the current. A spot of sample is placed in the center of the strip. When the current is applied ions separate out and migrate toward the attractive electrodes (Figure 2). Paper electrophoresis has several limitations. Only small charged molecules can be reliably separated since many macromolecules adsorb on to the paper, although it is possible to reduce the adsorption by using a buffer that is more alkaline than the isoelectric point of the sample. Paper systems are associated with high electrical resistance causing heating that dries out the paper. Although this method has been largely superseded by gel methods for many samples it is still useful for separation of small molecules such as amino acids, small peptides, nucleotides, and inorganic ions. An important limitation to this technique is that considerable diffusion of small molecules occurs at low voltage.

**Figure 2** Paper electrophoresis (low voltage). A paper strip is soaked in buffer (using connecting wicks). It is important that the paper remains wet. When a spot of sample is applied to the strip, and an electrical field applied, ions will migrate toward the attracting electrode.

### Paper Electrophoresis (High Voltage)

For the electrophoresis of small molecules it may be beneficial to use a high-voltage system. This results in better resolution and rapid separations (10–60 min). The voltage supplied can be up to 10 000 V, which produces a great deal of heat making it essential to have a direct cooling system. This method has been used to detect drug metabolites in urine, and for the separation of oligosaccharides, and peptides.

### Cellulose Acetate Electrophoresis

Commercially available cellulose acetate sheets have a homogeneous micropore structure. Unlike paper, very little adsorption occurs. Cellulose acetate is less hydrophilic than paper and so less buffer is held in the medium, leading to shorter separation time and better resolution than paper and less sample required than with other mediums. The cellulose acetate sheet must be saturated with buffer prior to electrophoresis. This is done by floating the strip on the surface in a shallow tank, since rapid immersion can trap air bubbles in the medium. The relatively low amount of buffer held by the sheet can lead to excessive heat production and drying out. Cellulose acetate electrophoresis plays an important role in clinical diagnostics, for example, in the analysis of hemoglobin. It is also commonly used in the separation of other blood proteins, enzymes, mucopolysaccharides, urine, and other bodily fluids.

### Thin-Layer Electrophoresis

Thin layers of silica, alumina, or cellulose can be prepared on glass plates. Electrophoresis is carried out in a horizontal unit as for the cellulose acetate method outlined above. The thin-layer media are saturated with buffer by capillary action from the reservoir by the connecting wicks. The method is

rapid and gives good resolution and sensitivity. Cellulose medium has been used in the separation of polysaccharides and peptides.

### Starch Gel Electrophoresis

Starch gel is made by boiling hydrolyzed potato starch in a buffer and pouring the molten starch into a preformed mold to cool. Gels of varying pore sizes can be made by altering the percentage of starch to buffer, although an exact pore size cannot be determined and batches can be inconsistent. Gels can be run either horizontally or vertically. A limitation to this gel type is that the starch possesses some charged groups that can cause adsorption of some macromolecules (e.g., proteins). An important application of starch gels is in allozyme electrophoresis (the separation of allelic variants of enzymes).

### Agar Gel Electrophoresis

Agar is a mixture of two galactose-based polymers, agarose and agarpectin. Agar will solubilize in aqueous buffers above 40°C and sets to form a gel at ~38°C. The gel has a large pore size and low frictional resistance enabling a rapid movement of ions, which assists in the separation of macromolecules. Agar gels can be used for separating nucleic acids at a lower cost than agarose gels (described next). A disadvantage to agar as a medium is that electroendosmosis is severe unless its sulfur content is removed prior to purification. Citrate agar electrophoresis is routinely used clinically to identify hemoglobins, for example, in diagnosis of sickle cell anemia.

### Agarose Gel Electrophoresis

Agarose is a polysaccharide derivative of agar. Gels are made by heating up agarose in an appropriate buffer. The gel contains microscopic pores that act as a molecular sieve. Certain molecules can also interact with agarose to varying degrees affecting their mobility. The higher the concentration of agarose the better the resolution. One per cent agarose is commonly used. The agarose gel is kept submerged under buffer in a horizontal apparatus, and for this reason it is sometimes called submarine electrophoresis, although it is possible to run agarose gels in a vertical apparatus. Nucleic acids are commonly separated by agarose gels and they are useful for DNA mapping and apoptosis ladder assays. As DNA and RNA have a constant charge to mass ratio (above 400 bp), separation is based on size and shape, not charge. Agarose gels are normally neutral, but in certain circumstances alkaline gels are used, e.g., for separation of nucleic acids as single strands. RNA preparations can be separated using a denaturing agarose gel. Low

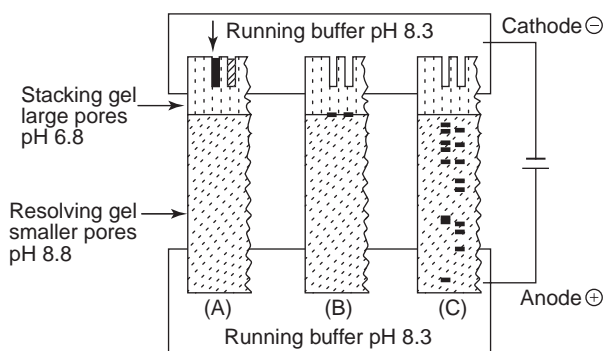

melting point (LMP) agarose is used for preparative gels. DNA fragments can be cut from the gel and the LMP agarose easily removed without causing strand separation due to its LMP. Very small fragments of DNA (less than 100 bp), are better resolved using the finer mesh of polyacrylamide gels.

### Polyacrylamide Gel Electrophoresis

Polyacrylamide gels are made by chemical polymerization of a mixture of acrylamide and bisacrylamide (a cross-linker) in the presence of a catalyst and an initiator of the polymerization reaction. The porosity of the gel is determined by the relative concentration of acrylamide to cross-linker and by the total percentage of monomers. The final concentration of acrylamide depends on the sample under study with high acrylamide concentrations giving better resolution of low molecular mass proteins, and vice versa. The gels can be prepared with a high degree of reproducibility. It is possible to finely tailor the gel pore size, for example, by preparing gradient gels where the acrylamide concentration can vary from 5% to 20% in the same gel, making it possible to separate a mixture of molecules with very varying molecular mass values. By varying gel and buffer parameters it is possible to separate samples on the basis of charge, size, or a combination of charge and size. Gels can be formed into either tubes or slabs and can be used for analysis or preparatively. Polyacrylamide gel electrophoresis (PAGE) is routinely used for protein analysis, and can also be used to separate nucleic acid fragments smaller than 100 bp. Nucleic acids are usually analyzed using a continuous buffer system where there is a constant buffer composition, pH, and pore size throughout the gel. Native proteins can be separated according to differences in their charge density, so long as the buffer in the gel is suitable for maintaining the protein in its native state. This enables enzyme preparations to be assessed for purity and also allows their activity to be assayed after the separation.

### Discontinuous PAGE

Discontinuous PAGE is a means of enhancing the high resolution of PAGE for analysis by focusing the sample into very sharp bands before entering the running gel, and is a common method used for proteins. It involves gels of two different pore sizes: the stacking gel has a larger pore size than the resolving gel below. The stacking gel offers little resistance to the passage of large molecules, which results in the concentration of the proteins at the interface between the two gels, thus giving a better resolution. There are also different buffer ions in the gel compared to

**Figure 3** Discontinuous polyacrylamide gel electrophoresis: (A) Sample is applied to the wells (solid arrow). (B) When current is applied, the sample concentrates at the gel interface. Proteins are stacked according to mass. (C) Molecular sieving occurs when the sample enters the resolving gel.

those in the electrode reservoir, hence the name discontinuous PAGE. These may differ in pH and/or buffer composition, and also assist in the focusing of samples before they enter the resolving gel (Figure 3). It is possible to use this system to get a good separation of a large sample volume.

### SDS-PAGE

Sodium dodecyl sulfate (SDS)-PAGE is a method used for separating and identifying proteins according to their molecular mass. Protein mixtures are boiled in a buffer containing SDS and a reducing agent. SDS is a detergent with a strong negative charge, which binds avidly to all proteins regardless of their natural charge. So, all proteins will carry a strong negative charge. The SDS binds to polypeptides with a constant weight ratio; therefore, the charge per unit mass is nearly constant and electrophoretic mobility becomes a function of molecular mass only (with a number of exceptions, e.g., glycoproteins, very basic proteins). The reducing agent breaks the disulfide bonds and the compact three-dimensional shape of the protein is changed to a rod-like structure. Separation is therefore not affected by the proteins' tertiary structure. The proteins are loaded onto a polyacrylamide gel, commonly a discontinuous gel system.

### Isotachopheresis

Isotachopheresis is a technique based on the principles of moving boundary electrophoresis. Two buffer systems are used: a leading electrolyte and a trailing electrolyte. The leading electrolyte has a higher mobility than the fastest sample component; likewise the trailing electrolyte has a slower mobility than the slowest component. When an electric field is applied

the leading electrolyte moves quickly toward the appropriate electrode with the sample ions following, creating zones in order of their mobilities. This method can only be used for either anions or cations, not both at the same time. Any charged substance can be separated by isotachopheresis. Isotachopheresis is usually carried out in capillaries. This method has the advantages of no sample preparation, speed, and is applicable to a wide sample range. Isotachopheresis has been used for analysis of organic acids in silage, anions in urine and serum, inorganic ions in water, proteins, and amino acids.

### Isoelectric Focusing

This is a method of separating molecules according to charge, and to a lesser extent tertiary structure. Amphoteric substances such as amino acids and peptides possess charges that vary from a net negative charge at low pH, through zero at some intermediate pH, through to a net positive charge at high pH. The isoelectric point is the pH at which the molecule has a net zero charge. Amphoteric molecules can be separated in an electric field across which there is both voltage and pH gradients. A pH gradient can be created by using ampholytes that are small organic molecules with different combinations of basic and acidic groups so that each one has a separate  $pK_a$ . By using a mixture of ampholytes with a low pH solution in the anode reservoir and a high pH solution in the cathode reservoir, each ampholyte will migrate to a pH equal to its pI and buffer the pH at that point. The sample molecules will migrate until they reach their isoelectric point and be focused into sharp bands (Figure 4). IEF can be carried out in various media, but agarose is frequently used as it can be gelled with a very large pore size, so reducing molecular sieving effects. A low percentage acrylamide gel is also used especially when carrying out two-dimensional gel electrophoresis (see below).

### Two-Dimensional Electrophoresis

Two-dimensional electrophoresis is a powerful technique that combines two different electrophoresis techniques, separating molecules by two different properties, resulting in a greater resolving power than each technique alone. For example, IEF in the first dimension and SDS-PAGE in the second dimension will separate proteins according to charge, followed by molecular mass. In a mixture of proteins from a cell lysate, thousands of different proteins can be resolved. This is a useful method for peptide mapping. The method can also be used as a preparative tool to obtain peptides for amino acid sequencing and also for the purification of antibodies. Thin-layer

**Figure 4** Isoelectric focusing. Molecules are separated according to charge in an electric field across which there is both voltage and pH gradient. The pH gradient is formed using ampholytes.

electrophoresis in one dimension and chromatography in another can also be used in a two-dimensional separation method for proteins and nucleic acids, and is frequently used in peptide mapping.

### Immuno-electrophoresis

Immuno-electrophoresis is defined as the separation and identification of proteins based on differences in electrical charge and reactivity with antibodies. The separating medium is usually an agarose gel. The gel has alternating wells and slots cut into it. The sample is placed in the wells and electrophoresis is carried out to separate the proteins. Antibody (or a mixture of antibodies) is added to the slots. The antibody and antigen migrate toward one another and form precipitin arcs at the region of optimal concentration. The method is mainly used clinically to determine the blood levels of immunoglobulins, and aids in the diagnosis and evaluation of the therapeutic response in many disease states affecting the immune system and also in the diagnosis of multiple myeloma. A similar technique is called rocket immuno-electrophoresis. In this case the gel contains specific antisera. The protein precipitates with the antisera in a rocket-shaped pattern. The height of the peak (or area under the

curve) is proportional to the concentration of the protein.

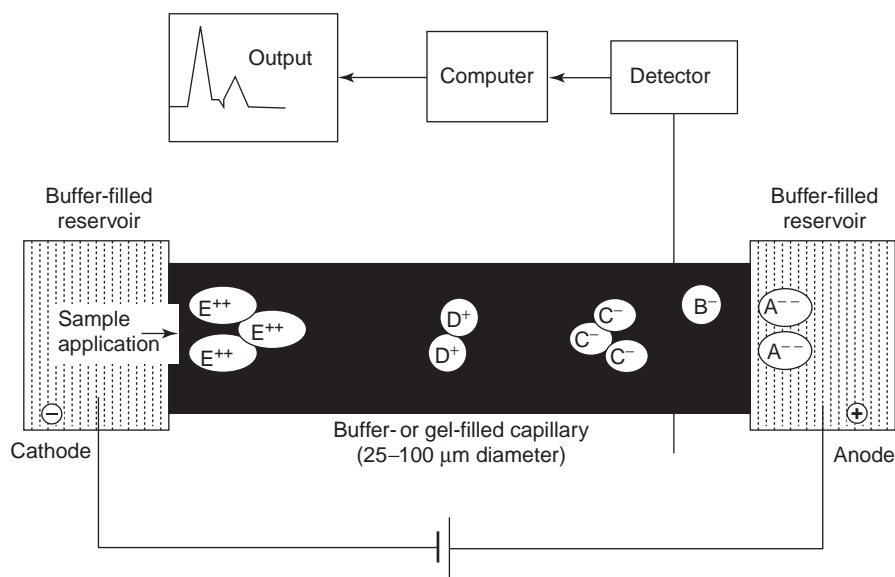

### Capillary Electrophoresis

CE separates samples by applying voltage across buffer-filled capillaries. The capillaries are usually made of fused silica with an external polyimide coating for increased mechanical strength. Capillaries are between 25 and 100 cm long with an internal diameter of 25–100  $\mu\text{m}$ . After passing through a detector the separated ions are seen as peaks (Figure 5). The area of each peak is proportional to the concentration of the molecule, which enables quantitative studies to be carried out. Advantages of CE are that analysis time is rapid: 1–30 min, and operating costs are low. Detection can be by a variety of methods depending on the sample. CE has become a range of techniques that include: capillary zone electrophoresis where separation is based on size and charge differences; capillary gel electrophoresis analogous to SDS-PAGE where separation is based solely on size; capillary isoelectric focusing, separation of neutral compounds using surfactant micelles (micellar electrokinetic capillary chromatography); and capillary isotachopheresis. Using these methods it is possible to use CE for separation of many different sample types, e.g., inorganic ions such as metal ions and anions (chloride, sulfate, and nitrate), DNA, serum proteins. CE is routinely used in a clinical setting, in the pharmaceutical industry, and also in forensic laboratories.

## General Operational Procedures

### Sample Application

Samples are generally applied using a micropipette or syringe. The position of application will depend on whether the sample contains components that will migrate to both electrodes. In this case the sample is usually applied to the center of the support medium as a spot or narrow streak and components will migrate in both directions. For samples where the components are all positively or negatively charged, sample application should be at one end of the medium farthest away from the attracting electrode. For a gel support medium the sample is usually applied to a well cast in the gel. For capillaries the sample is applied at one end furthest from the detector. This is usually achieved by dipping the capillary into the sample vial, the vial is then pressurized causing a volume to be forced into the capillary. Sample volumes used in electrophoresis can vary from  $1 \times 10^{-5} \text{ cm}^3$  (in CE) to  $5 \text{ cm}^3$  for some preparative separations.

**Figure 5** Capillary electrophoresis. As the ions migrate along the capillary, they pass through a detector. After integration, the separated ions are seen as peaks. Analysis is rapid: 1–30 min.

### Detection

Detection of unknown compounds or molecules after electrophoresis is usually *in situ*. Most biological molecules are colorless and need to be treated to produce stable colored compounds. Examples are the visualization of proteins in polyacrylamide gel with Coomassie Blue or silver stain. The medium can also be treated with compounds that bind to the sample causing them to fluoresce under ultraviolet (UV) light. Enzymes can be detected by histochemical methods where substrates are converted into insoluble colored products. It is possible to detect many biological compounds by immunological methods; for example, in western blotting the separated components are transferred from a polyacrylamide gel onto another suitable medium (e.g., nitrocellulose) that can then be treated with antisera and the conjugated product detected by various methods. If a sample contains radioactive components then the radioactive element can be detected by several different methods, e.g., phosphor imaging, fluorography. In CE, there are detectors built into the instrument to detect the peaks as they are resolved. The most frequently used is a UV absorbance detector. There are also fluorescence, conductivity, and indirect detectors available. It is possible to combine CE and mass spectrometry to obtain structural information about the resolved peaks, making this a very powerful technique.

A number of methods are used for recovering separated compounds from the support medium.

Cellulose acetate will dissolve in acetone leaving the separated compound in solution. Macromolecules can be recovered from starch and polyacrylamide gels by electrodialysis. In some forms of preparative electrophoresis the sample is run until the components ‘run off the end’ and can be collected.

### Introduction

Electrophoresis is a separation method that is based on the migration of charged species in a supporting medium (a liquid or a hydrophilic gel) under the influence of an electric field. The ability of electrophoresis to separate charged species ranges from small inorganic or organic ions to charged biopolymers (like DNA or proteins), or even chromosomes, microorganisms, or whole cells. Even though electrophoresis was established more than 100 years ago, it is an important technique even today. In the form of gel electrophoresis it is almost the only technique used for solving complicated separation tasks in genomics and proteomics, where thousands and thousands of species must be separated. Furthermore, in the last two decades electrophoretic techniques in capillaries or microchips have had a rapid development. Due to the fast expansion of new electrophoretic methods, many of the older terminologies now have rather different meanings than before. In this article, the basic principles are explained and discussed.

### Basic Terms

The supporting medium where electrophoresis takes place is called the electrophoretic system or the separation system. The separation systems are solutions of electrolytes that are filled into a separation column or a separation channel (Figure 1). Both ends of the column are connected with vessels, which are also filled with the solution of electrolytes and serve as a stock of the solution. The electric voltage (500–30 000 V), which is called driving voltage, is provided by two electrodes in the two vessels and

raises the driving electric field. The analyzed species (analytes) are introduced through a narrow sample plug, which then migrate across the longitudinal axis of the column in the liquid, the negatively charged analytes (anions) in the direction of the anode and the positively charged ones (cations) in the direction of the cathode. As various species have different velocities in the electric field, they are spatially separated from each other and are detected by a suitable detector, which is located at a certain position of the column or, sometimes, at its end. The separation column is often a very thin tube, with an inner diameter of 10–500  $\mu\text{m}$ , which is called the capillary; the electrophoretic methods that utilize such a capillary are called the capillary electrophoretic methods. The separation column can also be formed by a channel in various materials (glass, plastic, silica, etc.), which is fabricated by means of technologies normally used for the production of electronic microchips. These approaches are called ‘lab-on-a-chip’ technologies and electrophoresis that uses this approach is called chip or microchip electrophoresis.

A hydrophilic cross-linked gel (mostly polyacrylamide or polysaccharide gel), which is soaked with a solution of electrolytes, or a viscous solution of a linear polymer with an electrolyte, can also serve as the separation medium. Electrophoresis using such gels or polymeric media is called gel electrophoresis. The polymeric chains of the gel serve in most cases not only as a supporting medium but also influence to a great extent the movement of the separated species. The gels or solutions of linear polymers can also be filled into columns (channels), but as the structure

### Introduction

Electrophoresis is a separation method that is based on the migration of charged species in a supporting medium (a liquid or a hydrophilic gel) under the influence of an electric field. The ability of electrophoresis to separate charged species ranges from small inorganic or organic ions to charged biopolymers (like DNA or proteins), or even chromosomes, microorganisms, or whole cells. Even though electrophoresis was established more than 100 years ago, it is an important technique even today. In the form of gel electrophoresis it is almost the only technique used for solving complicated separation tasks in genomics and proteomics, where thousands and thousands of species must be separated. Furthermore, in the last two decades electrophoretic techniques in capillaries or microchips have had a rapid development. Due to the fast expansion of new electrophoretic methods, many of the older terminologies now have rather different meanings than before. In this article, the basic principles are explained and discussed.

### Basic Terms

The supporting medium where electrophoresis takes place is called the electrophoretic system or the separation system. The separation systems are solutions of electrolytes that are filled into a separation column or a separation channel (Figure 1). Both ends of the column are connected with vessels, which are also filled with the solution of electrolytes and serve as a stock of the solution. The electric voltage (500–30 000 V), which is called driving voltage, is provided by two electrodes in the two vessels and

raises the driving electric field. The analyzed species (analytes) are introduced through a narrow sample plug, which then migrate across the longitudinal axis of the column in the liquid, the negatively charged analytes (anions) in the direction of the anode and the positively charged ones (cations) in the direction of the cathode. As various species have different velocities in the electric field, they are spatially separated from each other and are detected by a suitable detector, which is located at a certain position of the column or, sometimes, at its end. The separation column is often a very thin tube, with an inner diameter of 10–500  $\mu\text{m}$ , which is called the capillary; the electrophoretic methods that utilize such a capillary are called the capillary electrophoretic methods. The separation column can also be formed by a channel in various materials (glass, plastic, silica, etc.), which is fabricated by means of technologies normally used for the production of electronic microchips. These approaches are called ‘lab-on-a-chip’ technologies and electrophoresis that uses this approach is called chip or microchip electrophoresis.

A hydrophilic cross-linked gel (mostly polyacrylamide or polysaccharide gel), which is soaked with a solution of electrolytes, or a viscous solution of a linear polymer with an electrolyte, can also serve as the separation medium. Electrophoresis using such gels or polymeric media is called gel electrophoresis. The polymeric chains of the gel serve in most cases not only as a supporting medium but also influence to a great extent the movement of the separated species. The gels or solutions of linear polymers can also be filled into columns (channels), but as the structure

**Figure 1** Schematic diagram of an electrophoretic instrument.

**Figure 2** Electrophoresis in slab gel.

of gels is cross-linked they are mechanically stable even without being filled into columns. Therefore, they are used in the form of flat strips or layers that are sticking to a supporting plastic or glass plate and are called slab gels (Figure 2).

## Mobility and Conductivity

When a charged particle of an  $i$ th species with charge number  $z_i$  is placed in the electric field with an intensity  $E$  (in  $\text{V m}^{-1}$ ), the Coulombic force  $F_c = z_i e E$  acting on the particle causes its movement;  $e = 1.602 \times 10^{-19}$  C is the elementary charge. As in electrophoresis the particles to be separated move in liquid or gel form, they face obstacles during the movement – mostly molecules of the solvent or polymer chains of the gel. The collisions and/or interactions with them causes the friction force  $F_f$ , which is proportional to the velocity of the moving particle, and which acts against the Coulombic force. After a very short time ( $10^{-13}$ – $10^{-10}$  s) both forces are balanced,  $F_c = F_f$ , and a mean velocity of the particle attains a constant value. The net movement of charged particles in the electric field is called electromigration and the velocity of such movement is called electrophoretic velocity. Various species have, under given conditions, a different electrophoretic velocity. When moving for a certain time, they are spatially separated. This is a separation principle of the majority (but not all) electrophoretic separation techniques. The electrophoretic velocity of the  $i$ th species  $v_i$  is almost perfectly proportional to the intensity of the driving electric field,  $v_i \sim E$ , when other parameters (e.g., temperature) are constant. The coefficient of proportionality is a quantity called electrophoretic mobility,  $u_i$ , and is defined as

$$v_i = u_i E \quad [1]$$

The dimension of the mobility in SI units is  $\text{m}^2 \text{V}^{-1} \text{s}^{-1}$ . The electrophoretic mobility is unique for a given species and is therefore tabulated for a
